The estimation of absolute population density is implicit rather than explicit in many population studies. Often, temporal or spatial differences in relative abundance are of greater interest than is population density per se. A temporal change is often expressed as a ratio of follow-up count or index divided by the baseline index or count. Suppose that a later trap capture rate is twice that of an earlier one: we would like to infer that the target species has doubled in density. The confidence limits on this inference can be approximated by regressing known ratios of absolute population densities on the corresponding ratios of relative population estimates. For example, we might find that the absolute population density changed from 1400/ha to 1700/ha, a ratio of 1.21. This is not exactly the expected ratio of 2.0, but some error is expected. In the absence of error, all corresponding ratios would be equal and therefore would lie on the line Y = X. If the points lie along a different slope, we can infer that the underlying conceptual model (i.e., constant detectability) is in error. Note that any comparison between two estimates involves at least two opportunities for inferential or estimation errors. Confidence limits on a comparison of estimates will therefore always be wider than the confidence limits on a single inference. In this paper we regress the ratios of all pairs of absolute abundances on the corresponding relative population measures to inspect the form of the relationship and quantify the precision of such inferences for each species.

Our data were collected during 1995–2000 with 38 total removal plots; 22 on the island of Guam, six on Rota, four on Saipan (Mariana Islands, western Pacific), two on Ile aux Aigrettes (Mauritius outlier, Indian Ocean), and four on Guana (north of Tortola, British Virgin Islands, West Indies). Total removal yields were partially reported in Rodda et al. (2001b), Rodda and Campbell (2002), and Rodda et al. (2005). Four of the 38 total removal plots were 5 × 5 m (0.0025 ha) and 33 others were 10 × 10 m (0.01 ha). The four small plots were obtained from the same area at the same time and, for the purposes of this study, were pooled to represent a single 10 × 10-m plot. The number of individuals captured per species per total removal plot ranged 0–676; nonzero captures per species averaged 21.5/plot (median = 6; sum of total removal captures = 4612). However, many of the lower species counts were omitted from consideration because of small sample size (see below).

We grouped all data into four habitat types: *Leucaena* forest, grassland, *Pandanus* forest, and broadleaf forest (Mueller-Dombois and Fosberg 1998). *Leucaena* forest is notable for the small size and translucency of leaves. *Leucaena* forests are relatively well lit, even in the shadows. *Pandanus* has very large, thick tangled leaves, which inhibit light penetration and create dark mesic forests. The broadleaf forest category included all other forestlands, which exhibited more average light and moisture conditions (unpubl. data).

Glueboard procedures followed Rodda et al. (1993). Glueboards were placed in a circular array of twelve traps on the ground in a ring concentric with the total removal plot at a distance of 5–10 m from the plot perimeter. Ground traps were spaced about 7 m apart. When used, 12 arboreal traps were stapled to a trunk or large limb at approximately breast height, one on the tree nearest each terrestrial trap. Traps were monitored for 24 h beginning at around 0830, but we found that relatively few captures were obtained from ground traps after the first 3 h of trapping. Therefore the capture results from ground traps reported here reflect three morning hours;

Table 1. Results of our analysis comparing absolute population estimates obtained from total removal plots to glueboard capture rates. The slope of best no-intercept regression indicates the detection rate multiplier ($1/\hat{p}$) achieved by glueboard sampling (lower values represent more complete sampling). The y-intercept indicates the constancy in detection over the ranges of densities sampled (higher y-intercept signifies reduced constancy).

Species	Relationship between absolute and relative abundance	Slope of best no-intercept regression	y-intercept (individuals/ha)
Anolis cristatellus	$r^2 = 0.88$, NS	15,840 (SE = 2900)	250 (NS)
Carlia fusca	$r^2 = 0.65$, $P < 0.0001$	4560 (SE = 680)	1511 ($P = 0.072$)
Emoia caeruleocauda	$r^2 = 0.55$, $P < 0.0001$	13,800 (SE = 2570)	1780 ($P = 0.028$)
Gehyra mutilata	$r^2 = 0.27$, $P = 0.016$	212,400 (SE = 78,600)	1330 ($P = 0.043$)
Hemidactylus frenatus	$r^2 = 0.83$, $P < 0.0001$	72,700 (SE = 8520)	350 (NS)
Lepidodactylus lugubris	$r^2 = 0.04$, NS	100,800 (SE = 24,800)	2930 ($P < 0.0001$)
Sphaerodactylus macrolepis	$r^2 = 0.82$, $P = 0.02$	368,300 (SE = 83,400)	10,400 (NS)

arboreal trap results reflect 24 h. Arboreal traps were omitted from three grassland plots and 17 other removal plots. The median placement of glueboards occurred within 19 days (range 1–78 d) of the total removal sample, generally afterwards. Total glueboard sample size for the three well-documented terrestrial species (see below) was 1025 captures in 1982 trap h. Glueboards were far less effective in trees, producing only 88 captures among four reasonably well-documented species in 19,252 trap h. Arboreal lizards were occasionally captured on ground traps; for example, the arboreal *Anolis cristatellus* was captured 9 times in 141.5 ground trap h.

Twenty-four species of lizards, snakes, and frogs were obtained by total removal, but only seven lizard species had sufficient glueboard captures to merit comparison between the techniques. Several of the omitted species warrant mention here: *Anolis carolinensis* was captured 35 times in total removal plots on Saipan, Rota, and Guam, but was caught only once on glueboards. This species thus appears refractory to glueboard capture, perhaps as a consequence of its excellent vision and deliberate movements as a sit-and-wait predator. Data from this species were analyzed through the ANOVA mentioned below, but not otherwise considered. *Bufo marinus* was taken on 45 occasions in total removal plots, but only once on glueboards. Our impression is that this species can routinely disable the glue in glueboards, perhaps by urination. The nocturnal arboreal gecko *Gehyra oceanica* was taken only once on glueboards, despite a sample of 90 individuals in total removal plots. This species ordinarily uses the surfaces on which we place arboreal glueboards and it is firmly grasped by glueboards; its scarcity among captures is therefore perplexing and may be related to its relatively deliberate locomotion. There was no evidence, such as skin remnants on traps, that this species freed itself from the glueboards. Glueboard capture data from *Lepidodactylus lugubris* were included in the following analysis despite our failure to capture it on glueboards in the vast majority of sites (detected by glueboards in only 4 of 31 sites where its presence was confirmed by 625 captures in total removal plots). This species is easily snared by glueboards, but it routinely travels over leaves and other very small diameter perches (Rodda et al. 2005), where placement of glueboards is difficult or impossible. Thus, the following analyses are based on the subset of species that are relatively easy to sample with glueboards.

We performed ANOVAs to identify the factors that influence glueboard capture rate. To be consistent with the proposed use as a metric of relative abundance, we forced the model intercept to pass through the origin (i.e., when the species was absent, capture rate was zero). Because we used a different time period for arboreal than terrestrial glueboards, we performed separate analyses for arboreal and terrestrial species. Furthermore, because we wanted to consider the role of island, we eliminated from ANOVAs all species that we recorded on only one island (i.e., *Sphaerodactylus macrolepis* and *Anolis cristatellus*).

We also regressed the absolute population density on the relative capture rates for each habitat sampled to inspect the form of the relationship and to identify 95% confidence limits for samples of the seven species with sufficient data (*A. cristatellus*, *Carlia fusca*, *Emoia caeruleocauda*, *Gehyra mutilata*, *Hemidactylus frenatus*, *Lepidodactylus lugubris*, and *S. macrolepis*). We had sufficient data for the two terrestrial skinks (*C. fusca* and *E. caeruleocauda*) to further consider the variability of capture rates within a single habitat type, *Leucaena* forest, on two and three islands, respectively. For all seven lizard species we also regressed logs of all pairwise permutations of ratios between non-zero absolute abundances on the corresponding log ratios of non-zero glueboard capture rates to inspect the form of the relationship and identify 95% confidence limits for samples. If each ratio between densities was exactly reflected in the corresponding ratio between trap capture rates, the ratios would lie on the line Y = X. Because the ratios were collected from pairs of plots, the number of ratios differs from the sample size of plots. For example, there are six pairs possible from four nonzero plots.

The ANOVA for terrestrial species indicated that density was associated with glueboard capture rate ($F_{1,35} = 7.99$, $P = 0.0077$), which also exhibited significant interactions with species ($F_{1,35} = 24.38$, $P < 0.0001$), species and habitat ($F_{1,35} = 3.34$, $P = 0.014$), and species and island ($F_{1,35} = 4.81$, $P = 0.0066$). Thus to obtain the most precise estimate of population density from glueboard captures, it would be necessary to calibrate the relationship separately for each habitat*island*species condition.

Five arboreal species were analyzed with ANOVA (*A. carolinensis*, *G. mutilata*, *G. oceanica*, *H. frenatus*, and *L. lugubris*). These did not collectively exhibit a significant relationship between total removal density and glueboard capture rate, although they did exhibit significant effects for habitat ($F_{1,35} = 7.32$, $P_{2,45} = 0.0018$), species ($F_{1,35} = 18.72$, $P_{4,45} < 0.0001$), and habitat*species ($F_{1,35} = 3.12$, $P_{7,45} = 0.009$).

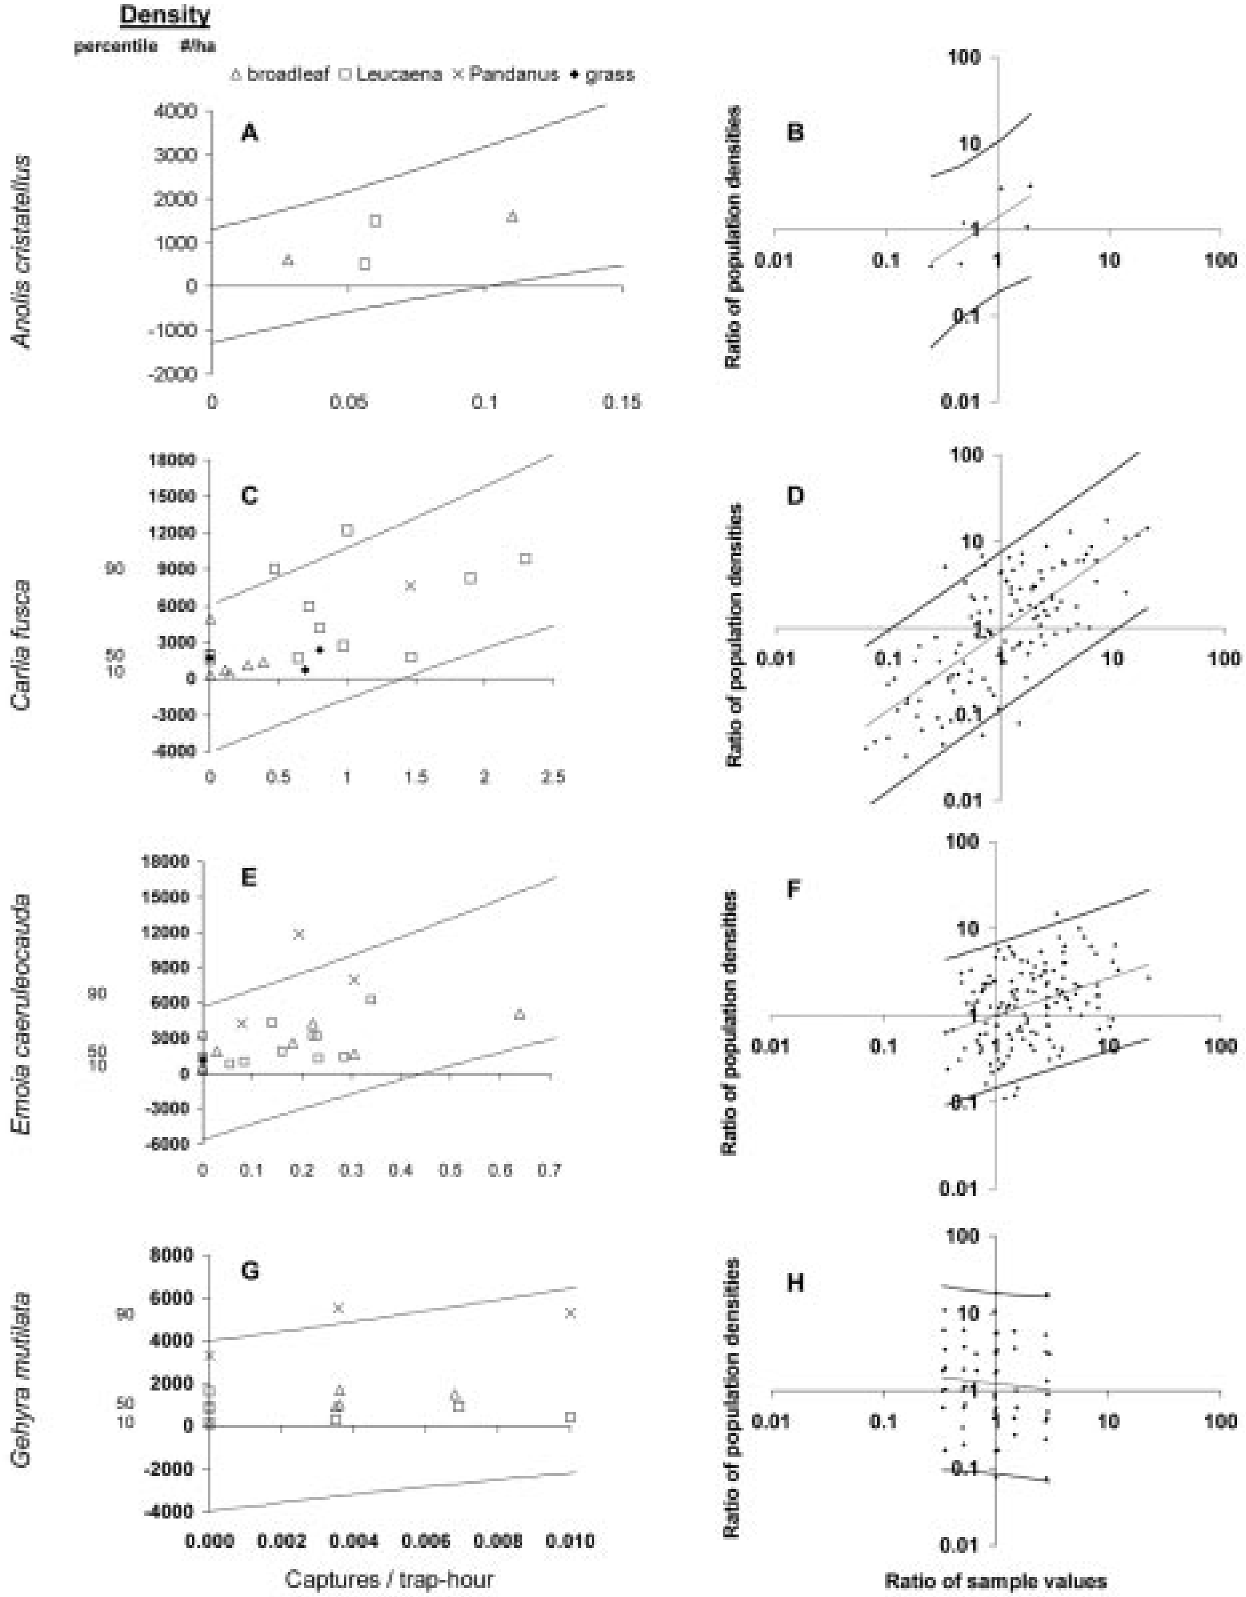

FIG. 1. Glueboard capture rates based on 12 traps for three morning hours for diurnal lizards (A–F), and 12 traps for 24 h for the nocturnal species (G–H). Left-hand graphs relate absolute densities to glueboard capture rates. Right-hand graphs relate pairwise ratios in absolute densities to pairwise ratios in glueboard capture rates. Because each possible pairing of points in the left-hand graphs yields a point in the right-hand graphs, the sample sizes are unequal, although based on the same information. The right-hand graphs are comparable among species, and are scaled identically to facilitate comparison. Outer lines in all panels represent 95% confidence limits for samples. (A) The relationship between absolute density (determined by 10 x 10-m total removal plots) and glueboard capture rate for *Anolis cristatellus* in two habitat types. (B) The relationship between pairwise ratios of *A. cristatellus* total removal population densities and the corresponding ratios of glueboard capture rates. (C–H) Other species as indicated by row headings.

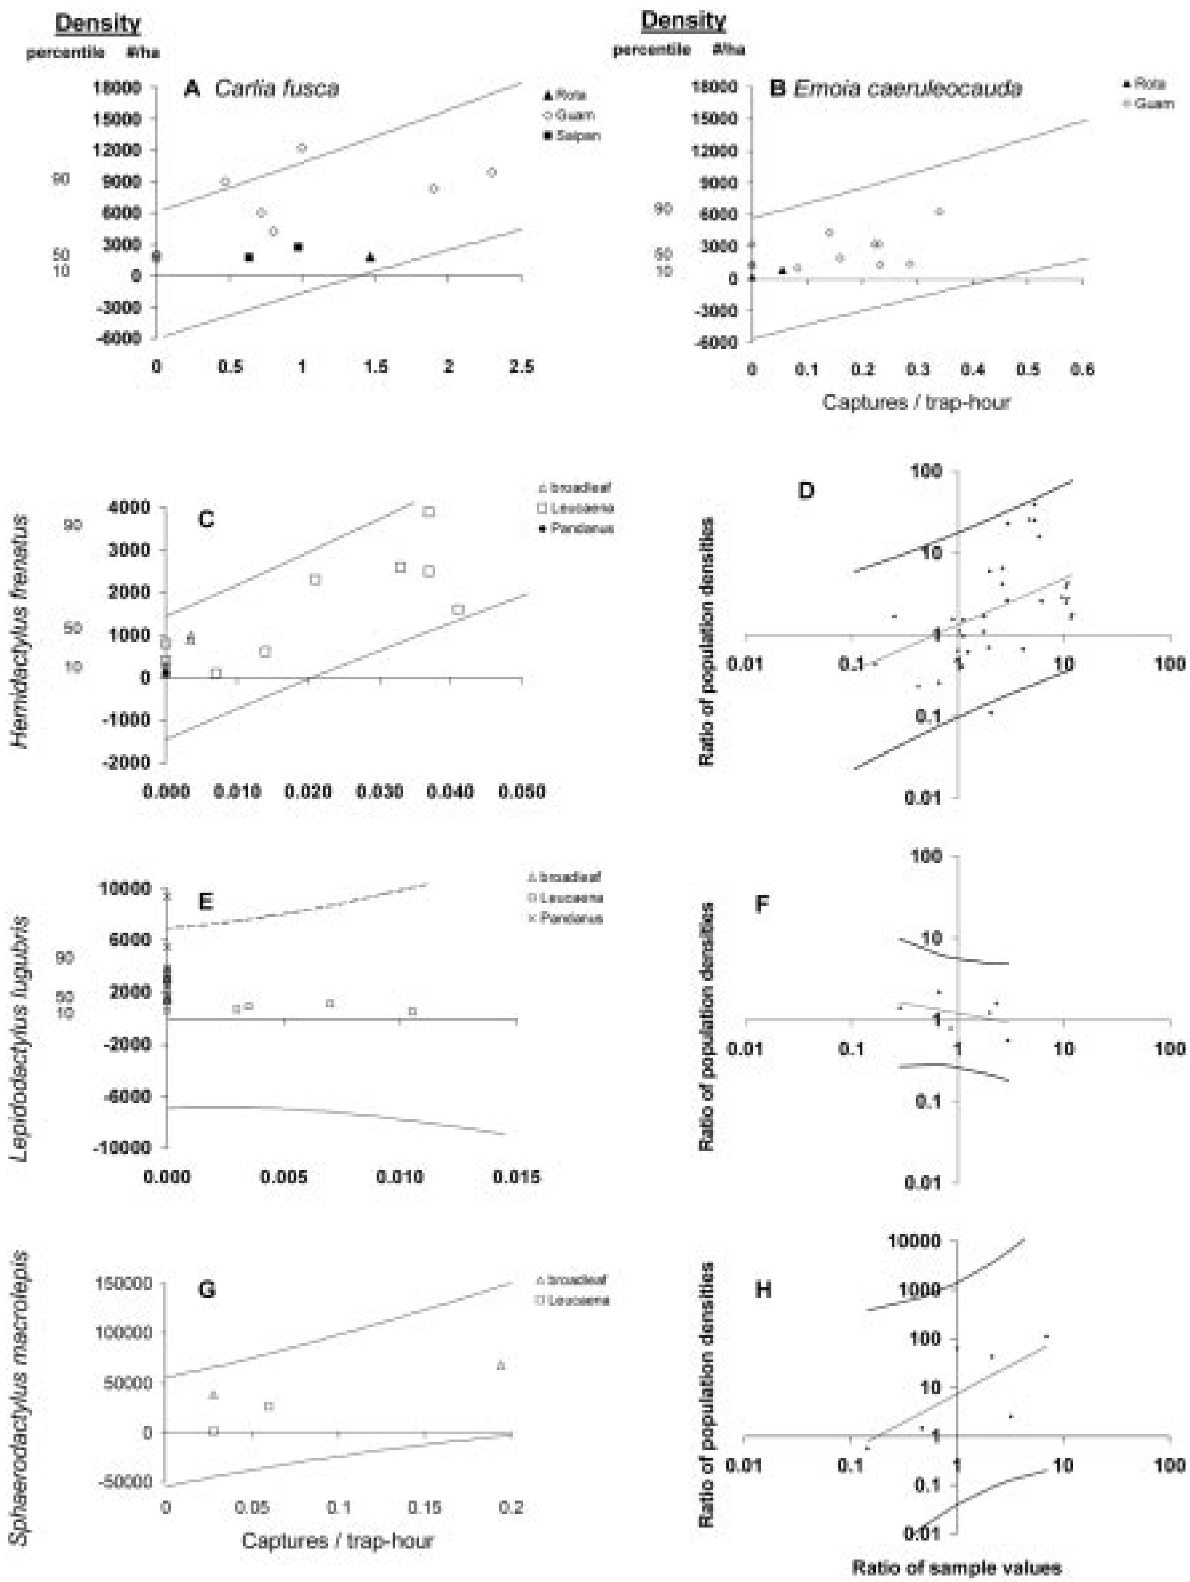

FIG. 2. (A) Relationship between absolute density and glueboard capture rates for *Carlia fusca* in a single habitat type (*Leucaena* forest) on three islands. See Fig. 1 left-hand column for graphical conventions. (B) Same relationship as A for *Emoia caeruleocauda* on two islands. The remainder of Fig. 2 follows the graphical conventions of Fig. 1. Note different scaling on ordinate for H.

The relationship between absolute and relative measures was significant for all but two species (*A. cristatellus* and *L. lugubris*), suggesting a reasonable correlation between methods (Table 1; Figs. 1, 2). However, of the five that were significant, three taxa (*C. fusca*, *E. caeruleocauda*, and *G. mutilata*) were relatively imprecise (r^2 < 0.7). Although an r^2 of 0.7 is satisfactory for many ecological studies, it does not produce adequate precision for correlated population densities estimates. This is most clearly seen from the percentile ranks associated with 95% confidence limits for mid-range capture rates (Table 2). Two of the seven taxa studied (*Anolis* and *Sphaerodactylus*) had confidence limits at mid-range that spanned the entire known range of densities for the species (0–100th percentiles). Four of the remaining five species covered 0–90th percentile or more. At mid-range glueboard capture rates, the best species as ranked by percentile range, *H. frenatus*, covered 0–84th percentiles of abundance, allowing only the inference that the highest population densities could be excluded on the basis of an intermediate glueboard capture rate. Thus, substantially larger sample sizes would be needed to make inferences about the density of these species from glueboard sampling.

TABLE 2. Confidence limits at midrange on the computed relationship between absolute population density and glueboard capture rates. The 95% CL are in units of absolute population density and the ranks give the corresponding percentiles from the observed range of densities for that species.

Species	Midrange capture rate (captures/trap h)	95% CL (individuals/ha)	Percentile range
Anolis cristatellus	0.06	0–2360	0–100
Carlia fusca	1.0	0–10,800	0–97
Emoia caeruleocauda	0.2	0–8500	0–97
Gehyra mutilata	0.005	0–4100	0–90
Hemidactylus frenatus	0.02	0–2940	0–84
Lepidodactylus lugubris	0.005	0–8070	0–97
Sphaerodactylus macrolepis	0.07	0–88,300	0–100

The y-intercepts of the absolute/relative correlations (Table 1) reflect the appropriateness of using glueboard capture rates to quantify the relative densities of populations within a single species, a comparison that assumes index values reflect a constant proportion of the sampled populations. The y-intercepts deviated significantly from the origin for four of seven taxa (*Emoia, Gehyra, Hemidactylus,* and *Lepidodactylus*), implying inconstancy in capture probability over the observed range of population densities. While not significant (based on N = 2), the large y-intercept for *Sphaerodactylus* (10,400 individuals/ha at zero glueboard captures) suggests that capture probability may be variable for this species as well (Table 1).

If index values such as glueboard capture rates are used to compare populations of a single species among different habitats, the y-intercepts associated with those different habitats must be close to zero and the absolute/relative regression slopes must be the same. Both ANOVAs (above) generally falsified this assumption. Too few data were obtained to test this hypothesis rigorously for individual species. However, inspection of Figs. 1 and 2 suggests that the main sources of the significant species*habitat effects may be *Carlia* in *Leucaena* habitat (Fig. 1C), and *Emoia* (Fig 1E), *Gehyra* (Fig. 1G), and *Lepidodactylus* (Fig. 2E) in *Pandanus* habitat. Each of these anomalies was associated with relatively reduced detectability (high absolute densities for low glueboard capture rates). The role of "island" in detectability was inspected with reference to *Carlia* (Fig. 2A) and *Emoia* (Fig. 2B). Although there was no apparent difference between islands for *Emoia* trapping in *Leucaena* forests, detectability of *Carlia* in *Leucaena* habitat appears to be appreciably higher on Guam than on other islands. On the basis of the small number of comparisons conducted, inter-island relative population estimates may be appropriate for *Emoia* but not *Carlia*.

The ratio plots (Figs. 1B, D, F, and H; Fig. 2D, F, and H) address the use of glueboard capture rates for detecting single population changes over time. Only three of the seven comparisons exhibited r^2 values > 0.25 (*Anolis, Carlia,* and *Sphaerodactylus*) but none was > 0.6 (Table 3). Six of the seven species had confidence limits that spanned about two orders of magnitude in abundance, but the limits for *Sphaerodactylus* were exceptionally wide (ca. six orders of magnitude). To be of any value for predicting population density trajectories from the observed change in glueboard capture rates, a ratio plot must have a slope of about 1.0, and a y-intercept passing through the origin (ratio = 1.0). *Anolis* and *Carlia* pass this standard and have relatively narrow confidence limits (spanning ca. two orders of magnitude). However, with such confidence limits one must observe a tenfold change in glueboard capture rates to be 95% certain of rejecting the null hypothesis of no population change.

Constancy of detectability between species is required for in-

TABLE 3. Characteristics of the relationships between absolute population density ratios and relative population density ratios. In these ratio diagrams, an axis value of 1 corresponds to population density equality or, for repeated samples, no temporal change.

Species	Relationship between absolute and relative ratios	Slope (significance test of slope = 1)	y-intercept (significance test of y-intercept = 1)
Anolis cristatellus	r^2 = 0.60, *P* = 0.07	0.87 (NS)	1.37 (NS)
Carlia fusca	r^2 = 0.53, *P* < 0.0001	0.92 (NS)	0.90 (NS)
Emoia caeruleocauda	r^2 = 0.13, *P* < 0.0001	0.99 (NS)	0.43 (*P* < 0.0001)
Gehyra mutilata	r^2 = 0.007, NS	Negative	—
Hemidactylus frenatus	r^2 = 0.25, *P* = 0.002	0.57 (*P* = 0.011)	1.3 (NS)
Lepidodactylus lugubris	r^2 = 0.18, NS	Negative	—
Sphaerodactylus macrolepis	r^2 = 0.52, NS	1.16 (NS)	7.4 (*P* = 0.049)

terspecific comparisons of glueboard capture rates. There was an 80-fold range in the glueboard detectability among well-sampled species (Table 1 slopes; Fig. 3). *Carlia* was the easiest to detect, followed by *Emoia* and *Anolis*. *Sphaerodactylus* and *Lepidodactylus* were nearly undetectable by glueboard sampling. No two of the tested species had detection multipliers that were sufficiently similar to support direct interspecific comparisons.

The general features of this comparison between glueboard capture rates and absolute population densities mirror those obtained from a similar analysis of the relationship between visual encounter rates and absolute population densities (Rodda et al. 2005). In both, high and moderately high r^2 values were associated with negligible precision in some population estimates. With both visual and glueboard detections we found that detectability sometimes differed appreciably among habitats. Furthermore, with both types of detections, species differed substantially in their detectability and in their suitability for single-species monitoring by means of relative population estimates. One hopeful note is that the rank order of detectability for tested species was the same for both methods. Whether detected by glueboards or visual searching, the five species with the most data were ranked (from most detectable to least) in the order *Carlia*, *Emoia*, *Hemidactylus*, *Lepidodactylus*, and *Gehyra*. In both cases *Carlia* was judged reasonably suitable for relative population estimation and *Lepidodactylus* was judged unsuitable. This correspondence of results suggests that some species will be easily sampled through a variety of methods, but it leaves no obvious avenue for estimating the abundance of problematic species such as *L. lugubris*. In contrast to the consistency between methods in relative detectability, visual quantification of *G. mutilata* was found to be especially favorable, whereas this species was found to be unsuitable for population estimation using glueboards. Thus given a choice between visual searching and trapping for population estimation of *G. mutilata*, visual searching is a clear preference.

A result such as that above may provide decisive guidance on selection of a monitoring program for a tested species, but it leaves open the question of whether one can extrapolate from these results to species or systems that have not undergone the costly validation tests performed here. The detectability differences summarized in Fig. 3 reinforce the generalization that no single unadjusted sampling method can be used interspecifically.

Even if small lizards differ in detectability among species, habitats, islands, and densities, it may be possible to use relative population estimators (index values) if the detection biases are predictable. Do basic niche dimensions clarify the range of detection possibilities? The first four species illustrated in Fig. 3 are arboreal, the latter three are terrestrial. The first species (*A. cristatellus*) and the last three (*Carlia*, *Emoia*, and *Sphaerodactylus*) are diurnal, the others nocturnal. Neither of these ecological distinctions appears to offer strong guidance on detectability (Fig. 3) or suitability for glueboard monitoring (Figs. 1, 2). Perhaps studies of additional species will clarify general patterns. In that regard, we find it notable that the two species of *Anolis* we tested differed so dramatically in detectability, despite the species being closely related, of similar dietary habits and size, and occupying similar positions in their habitats (both are primarily trunk dwellers where they were tested: *A. carolinensis* occupies canopy positions in its native range, but is typically found much lower on the small trees sampled in

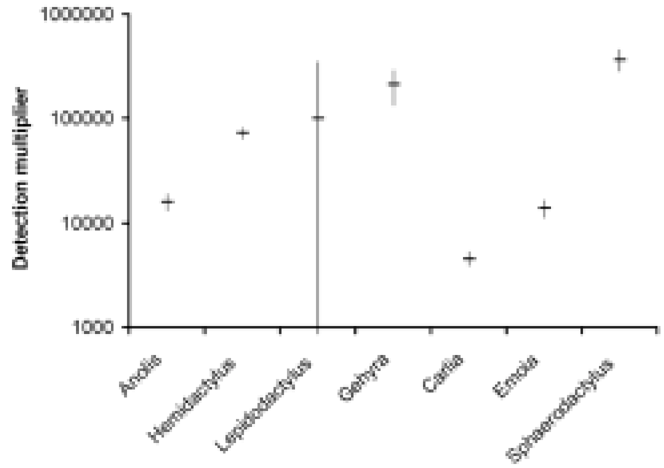

FIG. 3. Detection multipliers ((1/ $\hat{p}$) +/- SE) for the seven best-studied species.

the Mariana Islands; unpubl. data). *Anolis cristatellus* was the most detectable arboreal species that we sampled, and *A. carolinensis* was collected by glueboards so infrequently that we were unable to quantify its detectability. It seems likely that the relatively deliberate locomotion of *A. carolinensis* reduces its vulnerability to glueboard capture, but it is disheartening to recognize that general principles of detectability are unlikely to be discernible from knowledge of phylogeny, size, diet, and ecomorphology. Future generalizations about detectability may require data, such as the speed and mode of locomotion that are not routinely collected by researchers interested in estimating population size.

Analyses of detectability, proportionality, and precision are helpful in designing monitoring programs. With additional validation studies it may be possible to suggest some general guidelines for predicting the validity of specific sampling techniques. For example, our data hint that arboreal species may be less well suited than terrestrial species for glueboard estimates. Likewise, slow-moving species may be less suitable than species that run quickly. Simple arboreal habitats may be more suitable than dense, complex ones (e.g., *Pandanus* forest). Furthermore, arboreal species that are most often found on twigs and leaves appear less well suited than species that habitually use trunks. These patterns may prove to be illusory when additional sampling strategies are studied and validated, but they illustrate the types of generalities that should become available after further study. More work along these lines is needed to establish the precision of population estimates for specified samples of these species in the habitats under consideration. For the vast majority of herpetofaunal species, validation studies are needed for all circumstances under which relative population estimates might be used.

Acknowledgments.—We were ably assisted by E. Campbell, G. Perry, R. Rondeau, C. Clark, S. Kot, P. Fritts, and numerous appreciated volunteers. The Department of Defense Legacy Program, the Falconwood Foundation (through a grant to the Conservation Agency (J. D. Lazell)), and the U.S. Department of the Interior's Office of Insular Affairs provided financial support. Andersen Air Force Base (H. Hirsch), the Northern Mariana Islands' Division of Fish and Wildlife (A. P. Marshall, T. Cruz, N. Johnson), the Guana Island Hotel (H. Jarecki), the Mauritius Wildlife Foundation (C. Jones, J. Mauremootoo, S. Harris), and Naval Station

Guam (L. Morton) provided access to field sites. T. Kman provided graphics support. T. Stanley provided invaluable insight on analytical issues. T. Kman, J. Savidge, C. Guyer, T. Stanley, and R. Rondeau suggested improvements to the manuscript.

Validation of relative population estimates has rarely been attempted for reptiles (Rodda, *in press*). Validity is expensive and time consuming to test. However, the scarcity of validation examples is due, in part, to the absence of a discrete threshold for success. Across density extremes (zero to superabundance), it is difficult to imagine how a relative measure would fail to be at least loosely correlated with density. Precision, however, depends on the strength of the correlation.

In many situations, bias is more problematic than imprecision. A relative population estimator will give a biased result if the detected fraction of the population varies systematically among the conditions of interest. Species to be compared must have the same detectability; habitats to be compared must allow equal detectability of the target species, etc. The simplest situation, a single species in a single habitat type at a single time, will yield an unbiased comparison of density only if the detection fraction is constant across the range of densities sampled. This factor is rarely considered, but can be troublesome. For example, searchers detect a lower fraction of horned lizards when the animals or signs of their presence are scarcer (Henke 1998). At low densities, a higher proportion of the animals are overlooked.

These factors suggest that a relative population measure cannot be considered "validated" in an absolute sense; an estimator will be more or less accurate depending on context. In this paper we consider visual encounter surveys (Crump and Scott 1994) as a relative population estimator for brown treesnakes (*Boiga irregularis*), skinks (*Carlia fusca* and *Emoia caeruleocauda*), and geckos (*Gehyra mutilata*, *Hemidactylus frenatus*, and *Lepidodactylus lugubris*) in forest on Guam, Mariana Islands. For each species we quantified the precision of the relative estimator from the correlation between visual searching and a validated absolute density estimator. To assess the contexts in which use of a relative estimator would be appropriate, we tabulated the constancy of the detection fraction among and within species and present evidence on the constancy of the detection fraction between habitats.

Attributes of a good estimator.—A good relative population measure will not only be correlated with true density, it will also be proportional. That is, if the population doubles, the relative measure should also increase two fold. If the regression of true population density on visual encounter rate has a positive y-intercept, the detection fraction is not constant, and a minimum density of animals must be present, on average, before the species becomes visually detectable (Fig. 1). This condition indicates a reduction in detection fraction at low densities. Conversely, a negative y-intercept indicates a reduction in detection fraction at high densities.

Another approach to assessing proportionality is to inspect the correspondence between pairwise ratios of absolute population estimates against the ratios obtained from a prospective index of abundance such as visual sighting rate. Unbiased and precise estimators will produce an exact correspondence (i.e., all points will lie on the line Y = X).

A relative population estimator that is "valid" in the sense of being correlated with absolute density may nonetheless be of no use if the confidence limits associated with the correlation span all or most possible population densities. For example, consider a species that occasionally achieves absolute population densities as high as 2500/ha. If a moderate visual encounter rate (e.g., 2 sightings/h) corresponds to an estimated absolute population density of 900/ha, but that estimator is bracketed by confidence limits of 0–2400/ha, the relative estimator is not useful.

To provide a common metric for confidence limits of species of varying abundances, we introduce the use of confidence limits expressed as percentile ranks of density. Percentile ranks are good for characterizing non-normal distributions or comparing distributions of unknown shape. Single-species abundances are rarely normally distributed—ours were not. Use of percentile ranks makes it possible to compare the utility of visual encounter rates among species of differing density.

Validation studies compare the performance of a proposed

method (the test method) against a proven reference method. For the lizard species considered, we compared the visual encounter rates (test method) to total removal samples (Rodda et al. 2001) obtained concurrently from an adjacent area (reference method). For the snake species considered, we compared the visual encounter rates to mark-recapture population estimates obtained concurrently from the same 1-ha plots. The validity of mark-recapture was established for this system by comparing mark-recapture population estimates to two total trap-outs of all snakes from 1-ha areas surrounded by snake-proof fencing (Campbell 1996). Comparing a test method to a reference method on a slightly different geographic area entails some sampling error, which should be manifest in reduced precision of the estimation. In the case of the snake sampling (identical areas), there is some loss of precision associated with estimating rather than measuring the absolute population density with the reference method. Nonetheless, these comparisons are among the first to rigorously measure the bias and precision of a relative sampling technique.

Sites.—Time-constrained visual encounter surveys (Crump and Scott 1994) and total removal sampling (Rodda et al. 2001) were conducted in three regions of Guam, Mariana Islands, 1993–97. Compared to a "region," a "site" was a small (~ 1 ha) area within which visual surveys were conducted and one or more very small (~ 0.01 ha) total removal "plots" were laid out. Because visual surveys required more space than total removal plots, the geographic correspondence between these two methods was only partial, although an effort was made to establish sample plots and visual survey routes in habitat that was representative of the entire site (see below).

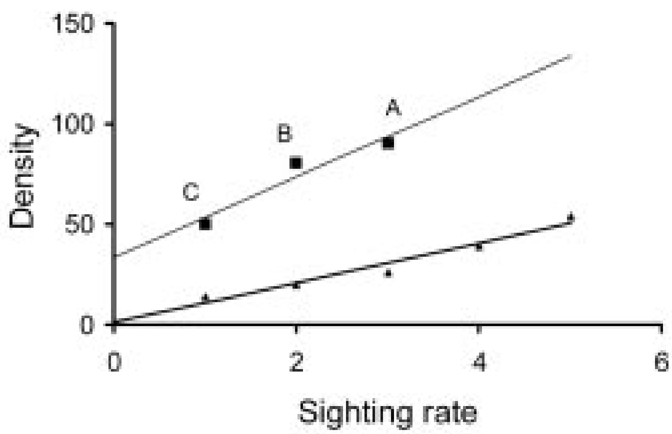

FIG. 1. Two hypothetical data sets expressing the relationship between relative and absolute population estimates. The detection fraction associated with each point is the point's X value/Y value (or sighting rate/true density). Point A's detection fraction, 3/90 = 0.033, is higher than the detection fraction at B, (2/40 = 0.025), which is in turn higher than the detection fraction at C (1/50 = 0.020). In a case such as this, in which detection fraction is reduced at progressively lower absolute population densities, the y-intercept of the associated regression line will be positive. In contrast, if the detection fraction is essentially constant vis-à-vis density (e.g., triangle points), the regression will pass through the origin (y-intercept = 0). The inverse of detection fraction (detection multiplier = Y value/X value) for a given point is equal to the slope of an imaginary line drawn from the point through the origin. Data sets composed of points with a constant detection fraction will therefore all lie along the same radial line and that line will pass through the origin.

Mark-recapture population estimation for snakes was performed quarterly at four sites in one of these regions (N 13.63, E 144.86) from 1993–94 (Campbell 1996). This habitat was scrubby secondary growth forest, consisting primarily of *Leucaena leucocephala*, an introduced legume tree having short stature (canopy heights 5–6.5 m) and tiny leaflets (3–4 x 5–8 mm). The three other sites were located in two regions of native forest, which supported a diverse array of trees, many of which had large leaves (e.g., *Pandanus* leaves up to 150 x 2000 mm; the dissected leaves of coconut palms may exceed 13 m in length). Visibility was reduced to a greater extent by the dense foliage in the large-leaved forest. Measured canopy heights were 9–15 m in the northern native-forest plots (N 13.65, E 144.86), and 5 m in the southern native-forest plots (N 13.35, E 144.67). For the purposes of our habitat analysis, sites were grouped into small-leaved forest and large-leaved forest.

Species.—Three small (1.0–2.2 g) arboreal nocturnal species of gecko were sighted with sufficient frequency for analysis: *Gehyra mutilata*, *Hemidactylus frenatus*, and *Lepidodactylus lugubris*. Two small (1.6–3.1 g) diurnal terrestrial skinks were sighted often enough for limited analysis: *Carlia* cf. *fusca* and *Emoia caeruleocauda*. The single snake studied, *Boiga irregularis*, is nocturnal and arboreal (Rodda et al. 1999b). It reached highest densities in the small-leaved habitat (Rodda et al. 1999c).

Reference population estimation.—Lizard abundance was estimated from total-removal plots (Rodda et al. 2001). This method involved erection of a lizard-proof fence during times when the species were inactive, and removal of all vegetation down to mineral soil while inspecting each item of vegetation for the presence of lizards (none of the sampled species permanently evaded capture by hiding below the surface). Thus the lizards were censused rather than surveyed in the sample plots. Of the seven sites under consideration, one was sampled by four 5 × 5 m plots, five were sampled with one 10 × 10 m plot, and one was sampled by two 10 × 10 m plots. The total number of lizards (of the five focal species) sampled per site averaged 147 (range 53–244).

Mark-recapture was used to obtain 29 estimates of absolute population densities of snakes (four sites sampled quarterly for two years). Sites were sampled daily for 15–32 d. Snakes were captured by hand and in standard brown treesnake traps (Rodda et al. 1999a), marked with PIT tags and released. Abundance estimates were obtained using the program MARK (White and Burnham 1999) under a size-stratified open model, using the relationship $N = \bar{n}/\hat{p}$, where $\bar{n}$ is the size-stratified mean number of daily captures, and $\hat{p}$ is the model's best estimator for that size class' average capture probability per day. Capture probability did not exhibit heterogeneity over time or by sex. As these plots were surrounded on all sides by 3–4 m swaths of mowed grass, and perimeter traps did not generally exhibit elevated capture probabilities, the nominal trap area (1 ha) was used for the estimation of density from abundance.

Test population estimation based on visual encounter surveys.—Experienced (> 100 h of previous surveys for these species in these habitats) reptile searchers conducted all visual encounter surveys. Observers walked forest transects at a slow speed (ca. 0.5 km/h), recording all reptiles seen on one side of a road or trail during surveys lasting 1–4 h. Nighttime surveys were conducted under

the illumination of a headlamp (various manufacturers). Each comparison between an absolute population density and a visual encounter survey mean represents 2.5 km of transect (snakes) or 5.6–76.5 person hours of lizard searching (mean 31.1 h). The transect lines used for the small-leaved habitats were serpentine paths at 25 m intervals through the 1 ha sites from which mark-recapture estimates were obtained (total removal plots were placed near the middle of the 1 ha plots, in representative vegetation). Vegetation was judged to be representative on the basis of plant species composition, canopy height, and canopy closure. The large-leaved habitats did not have suitable paths through the middle of the study sites; instead, primitive road edges passing to within 100 m of the total removal plots were surveyed for a distance of about 1 km. The roads passed through similar habitat, although the preference of *Carlia fusca* for disturbed habitat no doubt biased upwards the abundance of that species in the vicinity of the large-leaved habitat transects.

Analyses.—We asked six questions: (1) Are relative and absolute measures of abundance correlated?; (2) Are detection fractions relatively constant at different densities within a species?; (3) Is the detection fraction constant among species of small lizards?; (4) Is the detection fraction constant between habitats?; (5) What range of population densities correspond to the confidence limits at moderate visual sighting rates (i.e., how precise are the observed correlations)?; and (6) What confidence limits best describe the relationship between ratios of absolute densities and ratios of sighting rates?

In assessing the strength of the correlations between absolute and relative measures, we used a no-intercept model. We report a sample-size adjusted r^2, with the associated probability that the slope equals zero. To be conservative, all reported probability values are two-tailed, even for one-sided contrasts. We computed the regression of absolute population density on relative population estimator, because this is the direction of inference normally used for estimates of population abundances.

We did not have direct measurements of the detection fraction; therefore we could not directly test whether the detection fraction was different at higher or lower population densities. Instead, we tabulated the y-intercept values for unconstrained regressions of absolute population density on relative population estimators. A positive y-intercept would reflect a reduced detection fraction at lower population densities and a negative y-intercept would indicate the converse. The associated probability indicates the likelihood that the true value is zero for a given sample size. In addition, we express the y-intercept value in percentile scores of population density based on a mean of 28 (range 21–32) 10 × 10 m removal plots having non-zero densities. For example, the 90th percentile abundances of the study species, in ascending order, were *H. frenatus* (3500/ha), *L. lugubris* (4400/ha), *G. mutilata* (5300/ha), *E. caeruleocauda* (6300/ha), and *C. fusca* (9000/ha).

To address the question of whether the detection fraction was constant among species, we used the slope estimate (and SE) from the no-intercept regressions. The slope of the regressions is the inverse of detection fraction; therefore a high slope reflects a low detection fraction. It is perhaps easiest to think of the slope values as "detection multipliers." They are "multipliers" in the sense that one can estimate an absolute population density by multiplying the relative measure of abundance by the detection multiplier. For example, if the relative measure of abundance is 5 sightings/h and the applicable detection multiplier is 10, the estimated absolute density would be 5 × 10 = 50 individuals/ha. Thus detection multipliers are a convenient way to convert relative to absolute measures of abundance. Detection fraction captures the same information, but in less tangible quantities, usually small fractions.

In the case of the small-leaved habitats, our visual surveys were conducted entirely within the 1 ha sites, on trails having 1 km of trail edges (each survey was conducted on one side of a 0.5 km trail). Because the visual sighting rate was based on searches of exactly 1 ha, the same unit for which the absolute density is estimated, the detection multiplier in this case also expresses the number of individuals that were present for each individual seen. The number of overlooked individuals is the number present minus the number seen. A detection multiplier of 12 indicates that 11 unseen individuals existed in the area for each one sighted (detection fraction = 0.083). In the large-leaved habitats, the layout of 1 km visual search transects did not correspond to a 1 ha study plot, but the slope parameter reflects the same conceptual multiplier (each additional sighting corresponds to a density increase expressed by the slope value).

Sample sizes for quantifying detectability by habitat were sufficient for only *Hemidactylus* and *Lepidodactylus*. Because those species abundances were on different scales, reflecting different values in different habitats, we studentized (SAS Institute 1990) the residuals from each regression and compared the values of the *z*-scores between large and small-leaved habitats using a *t*-test after testing for equality of variances ($F = 3.84$; $P = 0.2$). To characterize the magnitude of the abstract scores in understandable units, we also report the mean detection multiplier for each species-by-habitat combination.

To characterize the precision of a relationship, we report the range of abundance percentiles corresponding to a midrange visual encounter rate. Confidence limits corresponding to negative population densities were truncated to zero.

The regression of $\log_{10}$ absolute abundance ratios on $\log_{10}$ sighting rate ratios produced confidence limits, slopes, and intercepts. Ratios were obtained for every pairwise permutation of nonzero values within a species. A proportional relative estimator will produce a slope of 1; therefore the slope was tested against the null hypothesis that it was equal to 1. The intercept has a less decisive interpretation, but proportionality requires that the Y = X line pass through the origin; we tested the null hypothesis that the y-intercept was equal to 0. The computed y-intercept appears in the figure at an axis value of 1, as log values were back transformed for easier visualization.

We were concerned that the very small sample sizes obtained for the two skink species would result in potentially misleading correlation coefficients and confidence limits. To assess the magnitude of the small sample bias, we randomly extracted 10 subsamples of various small sizes (N = 2, 3, 4, 5, 10, 20, and 50) from a 100-point random distribution having the slope, range, intercept, and r^2 values characteristic of our empirical data sets. Using ten simulations of each sample size we computed the mean and variance of range of confidence limits (at mid slope), adjusted r^2, and slope.

Were absolute densities correlated with sighting rates?—A positive relationship was evident for all species except brown

treesnakes (Fig. 2), for which the relationship was insignificant ($r^2 = 0.005$, NS). Although the regression is strongly influenced by two outliers (Fig. 2), the relationship is comparably weak with those outliers removed. The correlation between absolute and relative estimators was equivalent between observers (Fig. 2).

Four of the five lizard species exhibited a tight correlation ($r^2 > 0.9$), and three of these five were statistically significant (Table 1). However, the sample sizes (N = 2) for *Carlia* and *Emoia* were small. Based on our simulations of equivalent (N = 2) samples, the bias associated with r^2 in such small samples is trivial (our simulations produced an average r^2 0–2% less than the full data set).

Was the detection fraction constant at different densities within a species?—All six species exhibited a positive value for the y-intercept, although the difference was slight and statistically significant only for *Lepidodactylus*. Our simulations of small sample sizes indicated a small (5–7.5%) bias towards steeper slope at sample sizes of N = 2. This implies that large-sample y-intercepts for the skinks would be larger than that observed. The significant discrepancy for *Lepidodactylus* was the greatest observed (60th percentile). On average, about 2065 individuals of this species would be present in a hectare before the first *Lepidodactylus* was seen.

The regression of absolute population density ratios on sighting rate ratios (Fig. 3) had a slope of 0.40, significantly less than the desired slope of 1 ($P < 0.0001$). The intercept (0.62) also deviated significantly from zero ($P = 0.0037$). These results indicate that the detection fraction was lower at lower densities.

Was detection fraction constant among species?—The average detection multiplier for each species ranged from the relatively detectable *C. fusca* (mean detection multiplier = 12.88 (SE = 2.80); detection fraction = 0.0776) to the rarely seen *G. mutilata* (mean detection multiplier = 6105 (SE = 412.9); detection fraction = 0.00016). In descending order of detectability the three other species were *E. caeruleocauda* = 91.8 (SE = 14.1), *H. frenatus* = 143 (SE = 17.7), and *L. lugubris* = 848 (SE = 271.7). The wide gaps between detection multipliers (relative to SEs) reinforce the inference that detection is grossly different among species.

Was detection fraction constant between habitats?—Tests comparing large-leaved and small-leaved habitats for *Hemidactylus* and *Lepidodactylus* indicated that both geckos were seen significantly less often in the large-leaved habitat ($t = 2.55$, $df = 11$, $P = 0.027$). For *Hemidactylus*, the mean detection multiplier in small-leaved habitats was 163 (SD = 54), about an order of magnitude less than that for large-leaved habitats, 1511 (SD = 703). *Lepidodactylus* was seen less often than *Hemidactylus* (higher detection multipliers on average), but exhibited a similar tenfold difference between habitats. In small-leaved habitats its detection multiplier averaged 984 (SD = 618), whereas that in large-leaved habitats averaged 9914 (SD = 5372).

How wide were the density confidence limits?—At moderate sighting rates *Lepidodactylus* and *Emoia* had density confidence limits that covered the full range of known densities (0–100th percentile) for the species. *Hemidactylus* and *Carlia* exhibited confidence limits that covered most of the known densities (0–90th percentile and 0–60th percentile, respectively). *Gehyra mutilata* was exceptional: a moderately successful visual survey (0.25 sightings/h) corresponded to a reasonably precise characterization of the

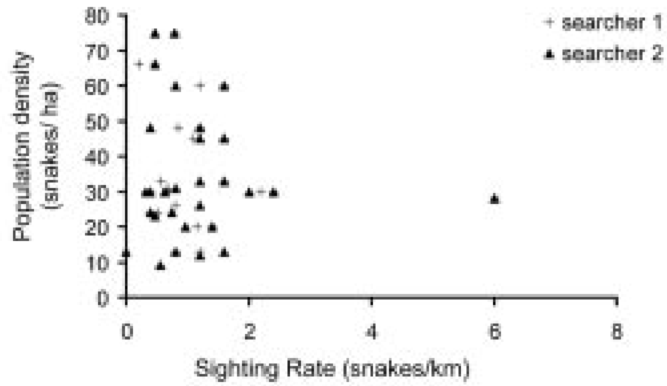

FIG. 2. The relationship between population density of *Boiga irregularis* in 1-ha *Leucaena leucocephala* forest, Guam, 1993–94 and snake sighting rates of two searchers searching each plot five times (total 2.5 km of searching per datum).

absolute density (50–70th percentile). The confidence limits for skinks are undoubtedly inflated by the small number of samples evaluated. Our simulations of two-sample regressions indicates that confidence limits for such small samples are 4.8–5.7 fold those based on 100 points; thus the width of the confidence limits for *Carlia* and *Emoia* need to be revisited when larger samples of comparisons become available. The other species have sample sizes that yield confidence limits only marginally larger than asymptotic values.

What confidence limits best describe the relationship between ratios of absolute densities and ratios of sighting rates?—The confidence limits associated with ratios were large, in keeping with the double inference being made (that both baseline and follow-up measurements were accurate reflections of true population density). For example, if the second measurement had been tenfold that of the baseline value, the naïve expectation would be that the population had increased tenfold. Instead the confidence limits range 0.33–7.5, indicating that the population could have shrunk by as much as threefold (ratio: 0.33) or increased by as much as 7.5-fold, although the most likely change was of a modest increase of about 60% (1.6-fold). The failure of the confidence limits to include the naïve expectation highlights the observed deviation from constant detection at different population densities. The wide confidence limits highlight the weakness of the double inference associated with ratios. Note that the absolute density ratio of 1 (no population change) is within the confidence limits for all of the sighting rate ratios considered (0.1–100 fold).

The overall analysis suffers from small sample sizes and incomplete geographic correspondence between test and reference plots. Thus it is encouraging that five of six species exhibited reasonably tight ($r^2 > 0.5$) positive correlations and four of five lizards exhibited very tight ($r^2 > 0.9$) correlations between absolute and relative population estimators. The presumption underlying single species relative abundance measures appears generally valid. The apparent exception is brown treesnakes, for which no correlation was evident. Our prior experience (e.g., Rodda et al. 1999c) using larger samples of visual sightings of brown treesnakes suggests that the fundamental premise is correct for brown treesnakes, but the effort contributing to each individual datum in the present study was inadequate (Rodda and Fritts 1992). Although each da-

TABLE 1. Correspondence of absolute population estimates obtained from mark-recapture (*Boiga*) or total removal plots (all lizards) to visual encounter surveys. An ideal visual survey would exhibit $r^2 = 1$, 95% confidence limits (CL) at midrange that were very narrow and near 50%, and a y-intercept near zero in both absolute density and percentile of abundance.

Species	Relationship between absolute and relative abundance	N	95% CLs at Midrange Sight Rate (percentiles)	Y-intercept	
				Individuals/ha	Percentile
Boiga irregularis	$r^2 = 0.005$, NS	58	Not applicable	36 (NS)	28
Carlia fusca	$r^2 = 0.91$, NS	2	0–60	216 (NS)	7
Emoia caeruleocauda	$r^2 = 0.95$, $P = 0.097$	2	0–100	137 (NS)	12
Lepidodactylus lugubris	$r^2 = 0.56$, $P = 0.021$	7	0–100	2065 ($P = 0.01$)	60
Hemidactylus frenatus	$r^2 = 0.90$, $P < 0.0002$	7	0–90	487 (NS)	45
Gehyra mutilata	$r^2 = 0.97$, $P < 0.0002$	4	50–70	114 (NS)	14

tum summarized five passes by each observer (2.5 km of visual searches), and although the snake is exceptionally abundant in the study habitat, 2.5 km of visual searches appears to be insufficient to accurately characterize density. The higher density of lizards, combined with the more extensive surveying effort for them ($\bar{x}$ = 31.1 h) apparently sufficed to produce strong positive correlations between relative and absolute population measures, although confidence limits were excessively wide in four of five cases. Additional validation work is needed to establish the sample size needed for an adequate level of precision.

Based on all six species exhibiting positive y-intercepts, and the low slope and nonzero intercept exhibited by the regression of ratios, we conclude that reduced detection fraction at low population densities may be a widespread problem with visual encounter surveys. Further investigation of this problem seems warranted, especially in light of the large magnitude of the intercept in some species (e.g., *Lepidodactylus*), and the high level of statistical uncertainty. On the basis of the information presented in this paper, we would not be comfortable with the assumption of proportionality for either *Hemidactylus* or *Lepidodactylus*. Further study into

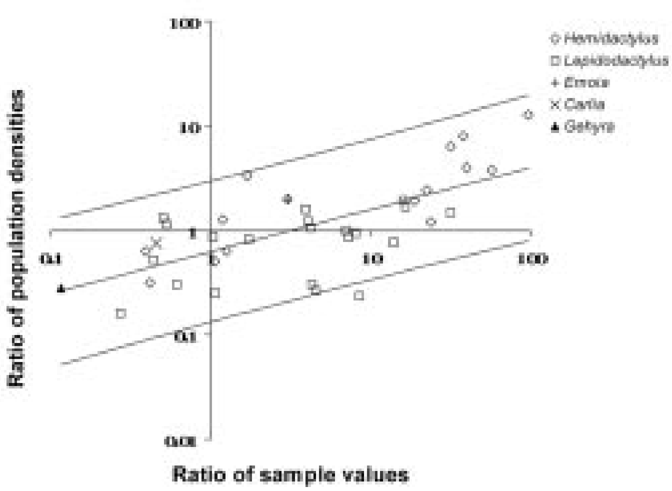

FIG. 3. The relationship between ratios of population densities and ratios of visual sighting rates for five species of lizard. All pairwise comparisons for non-zero values within a species are given, with the associated regression line and 95% confidence limits.

the magnitude and shape of the low-density decline in detection probabilities for those species may allow a correction factor to be incorporated for unbiased estimates.

The gross differences in detection multipliers or detection fractions among the species we studied indicate that relative population measures should not be used interspecifically to characterize abundances. Even species with similar sizes and habits (e.g., *Hemidactylus* and *Gehyra*) exhibited substantial differences in detectability within a single habitat type. We conclude that interspecific population density comparisons should not be based on visual survey data in the absence of validation studies that quantify the detection probabilities in the system of interest.

The difference in detectability of small geckos between habitats was about tenfold. The generality of this value is of great interest. Are habitats usually more or less similar in visibility of reptiles? Some rules of thumb would be useful for planning inventory and monitoring efforts.

We were discouraged by the wide confidence limits associated with the visual surveys we conducted. Based on the information presented, we would select visual surveys as an adequate sampling tool only for *G. mutilata*. Unfortunately, it is difficult to assess whether the reported confidence limits would be appreciably smaller if based on exhaustive visual surveys having a perfect geographic correspondence between test and reference methods. Further comparisons would be of interest, not only for the species we reviewed, but for other visually sampled species as well. It is perhaps notable that the species with the lowest detection rate, *G. mutilata*, was also the species with the most precise correlation between visual sightings and absolute density. The effective sample size was small, even for inferences limited to this species. Also, the bulk of the data for this species came from a single habitat type. Further study is needed to determine whether highly precise correlations are characteristic of certain species or habitats.

Acknowledgments.—We were ably assisted by J. Graham, M. Reid, T. Sharp, G. Beauprez, T. Mabee, S. Kot, and numerous appreciated volunteers. The Department of Defense Legacy Program and the U.S. Department of the Interior's Office of Insular Affairs provided financial support. Andersen Air Force Base (H. Hirsch) and Naval Station Guam (L. Morton) provided access to field sites. T. Kman provided graphics support. T. Stanley provided invaluable insight on analytical issues. T. Kman, J. Savidge, C. Guyer, T. Stanley, K. Dean-Bradley, and R. Rondeau sug-

gested improvements to the manuscript.

Radio telemetry is a valuable method for acquiring important ecological information such as home range, habitat preference, and dispersal distance for many types of wildlife (White and Garrott 1990). One of the limitations with using telemetry is the difficulty of developing a reliable and safe transmitter attachment technique to facilitate consistent research. Multiple transmitter attachment methods are available for a variety of lizards, with additional approaches being introduced as telemetry becomes increasingly popular and techniques are refined through trial and error (see Richmond 1998; Ussher 1999).

Using radio telemetry on saxicolous lizards living among jagged, xeric limestone conditions presents serious challenges for wildlife researchers. West Indian iguanas (genus *Cyclura*) are particularly difficult because they inhabit areas of sharp limestone and squeeze into small retreat openings, often causing the loss of externally affixed transmitters. Attaching external transmitters to hatchling or subadult iguanas also is problematic because of their small size and potential for rapid growth. Numerous radio transmitter attachment methods have been attempted, with variable results, on adults of this genus (reviewed in Goodman 2005), but none have been successful for hatchlings or juveniles.

We devised a technique for attaching radio transmitters to recently hatched Andros Iguanas (*Cyclura cychlura cychlura*) during a study of natal dispersal, survival, and habitat preferences. Data on these parameters are crucial for developing a science-based management program for this endangered lizard, especially since little ecological information is available for hatchlings of this species or its congeners.

We conducted our study from 12 August to 9 October 2003, and 3 August to 14 September 2004 on Andros Island, Bahamas, primarily in pine woodland, scrub, and mangrove habitats. Forty-one hatchlings in 2003 and 36 hatchlings in 2004 were collected for radio tracking directly from nests or from incubated eggs. Hatchlings ranged from 31 to 57 g in body mass (mean = 44; S.D. = 5.56), 84–106 mm in snout–vent length (mean = 97; S.D. = 0.41), and 122–171 mm in vent–tail length (mean = 153; S.D. = 0.97). To radio track lizards we used BD-2 (17 × 8.5 × 5.5 mm) and PD-2 (23 × 12 × 5.5 mm) model transmitters (Holohil Systems Ltd., Ontario, Canada). The average battery lifespan for the

BD-2 and PD-2 transmitters was 12 and 16 weeks, respectively. The BD-2 (1.9 g) and PD-2 (2.7 g) transmitters after encapsulation represented between 4.1 and 9.0% (mean = 6.0%; S.D. = 0.7) of hatchling body mass.

To test the efficacy of the attachment technique on another lizard species, we attached transmitters during the 2004 field season to three adult Curlytail Lizards (*Leiocephalus carinatus coryi*) inhabiting the same study sites and tracked them between 16 and 30 days. The lizards ranged from 39–45 g in body mass (mean = 42.7), 91–98 mm in SVL (mean = 95), and 127–151 mm in vent–tail length (mean = 139). The transmitters were between 4.9 and 6.0% (mean = 5.7%) of adult body mass.

The transmitters and batteries were encapsulated in an inert waterproof epoxy with tubes attached laterally through the anterior and posterior ventral edges. The antenna was a 20 cm long flexible stainless steel wire covered with a black nylon coating and shrink tubing to reinforce the base. Using a hand-held 3-element Yagi directional antenna and a Wildlife Materials, Inc. (Carbondale, Illinois, USA) TRX-48S receiver, we obtained a signal range of 500 m over open, flat terrain that was reduced to 200 m in closed forest conditions.

To attach a transmitter, two 15 cm pieces of 20 lb test monofilament line were cut (length may vary depending on personal preference and size of animal) and one piece inserted through the anterior and the other through the posterior tube of the transmitter. The transmitter was placed on the dorsal side of the pelvic girdle, the anterior monofilament line was wrapped around the lizard's body (anterior to the hind limbs) and tied with two square knots in the lateral inguinal region using needle-nose pliers. A dab of ethylcyanoacrylate glue gel was then applied to the knot to prevent it from slipping. The posterior monofilament line was then wrapped loosely around the tail, tied, and glued as above. All extra line was trimmed (Fig. 1). The antenna protruded farther than the tail tip, but appeared to have no effect on the animals. Although antennas can be trimmed, this will limit the maximum signal detection distance.

An assumption of radio tracking investigations is that animal movements are not affected by researcher techniques (White and Garrott 1990). Although not quantified, our method appears to have no significant effect on iguana behavior or movement. All hatchling iguanas ran, jumped, swam, and climbed trees without apparent difficulty. Lizards were found in pine trees 10 m above the ground, in underground (and at times underwater) limestone retreats, and within mangrove islands which required overwater movement. The Curlytail Lizards also appeared unaffected by the transmitters. The inert waterproof epoxy was gray in color and was relatively cryptic in our study environment. The epoxy can be painted to either facilitate detection by the researcher or to offer additional camouflage for the lizard.

Although no transmitters detached from the animals during the study, this technique does have limitations. Abrasions developed after two weeks in the inguinal region of five (12%) iguana hatchlings in 2003. When this occurred, we recaptured the lizard and reattached the transmitter on the ventral surface directly posterior to the cloaca using the method described above. Repositioning the transmitter removed pressure from the ventral inguinal region where the abrasions were occurring. Abrasions healed after one week and the new ventral transmitter placement appeared to have no effect on the movements, activity, or defecation ability of the hatchlings.

During the 2003 study, we noted that the posterior (tail) monofilament line often snagged on jagged limestone surfaces or tree bark as the lizards moved, thereby increasing cutting pressure on the

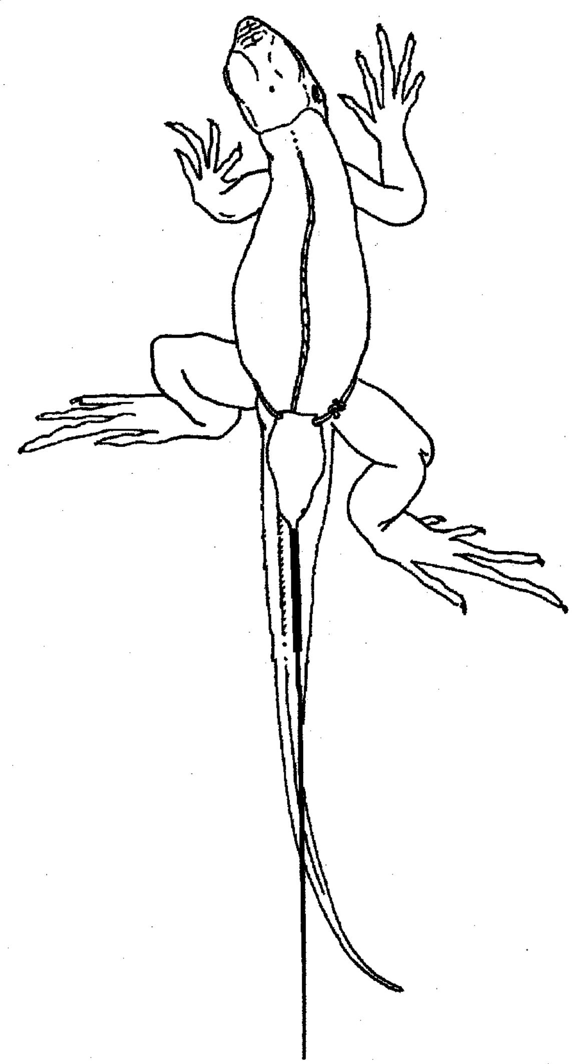

FIG. 2. Dorsal view of PD-2 transmitter attachment method with only the anterior monofilament line tied.

inguinal region. Therefore, we attached the last ten transmitters in 2003 and all the transmitters in 2004 without using the posterior monofilament line and secured the anterior (inguinal region) line more loosely (Fig. 2). This method also was effective, and in our opinion, was the better of the two options, as it allowed the transmitter to move slightly as the lizard moved, thereby reducing pressure on the inguinal region. The transmitter rotated on the body at times and occasionally flipped back and forth as the animals moved backwards then forwards in enclosed spaces. However, no abrasions were found during the remaining four weeks of the project in 2003 or throughout most of 2004. All surviving hatchlings in 2003 (N = 2) and 2004 (N = 8), as well as the three *Leiocephalus* in 2004, were recaptured at the end of this study and transmitters were removed. All recaptured iguanas had maintained, or gained body mass, were free of abrasions, and appeared healthy. One curlytail lizard, which was not recaptured until 30 days after initial attachment, exhibited slight cutting abrasions in the inguinal region.

No lizards died during this study directly as a result of the attachment method. Because very little material is required for this convenient and easy procedure, lizards can be harnessed in the field within minutes using only minimal equipment. However, we encourage using this technique only if lizards can be reliably recaptured. The monofilament line may not present a significant problem for adult lizards of equivalent size, but long-term survival of growing hatchlings will be affected if the line is not removed. Additionally, 83% and 61% of radio-tagged hatchlings were visually confirmed to be eaten by snakes in 2003 and 2004, respectively. Although we feel time of release after hatching may have influenced the higher than expected predation rates in 2003, we cannot exclude the possibility that the transmitter attachment played a role. The potential benefits of using this technique warrants further study with results being disseminated in the literature. A future modification could include inserting the monofilament line through low-diameter Tygon® tubing so that the potential for long-term cutting into the inguinal region of adult lizards is further reduced. In conclusion, use of this method allowed us to elucidate many previously unknown aspects of the behavior and ecology of *Cyclura* hatchlings (Knapp and Owens 2004), and should be applicable to other lizards of similar size.

Acknowledgments.—We thank C. Kenneth Dodd, Jr. and Allison Alberts for comments on early versions of the manuscript. We also thank Glenn Gerber and Bryon Wilson for critically reviewing the manuscript and offering welcomed suggestions. Coleman Sheehy III assisted with radio tracking during the 2004 field season. Funding for transmitters was made possible through the Chicago Zoological Society Board of Trade Endangered Species Fund, the International Iguana Foundation, and the Chicago Herpetological Society. Tiamo Resorts of South Andros provided logistical support during the study.

A New Technique for Capturing Pacific Pond Turtles (*Actinemys marmorata*) and a Comparison with Traditional Trapping Methods

PIERRE FIDENCI
Garcia and Associates (GANDA)
1 Saunders Ave, San Anselmo, California 94960, USA
e-mail: pfidenci@garciaandassociates.com

Various techniques have been used to capture freshwater turtles in the field, including hand collecting, dipnetting, snorkeling, fyke nets, baited hoop nets, collapsible traps, basking traps, and funnel traps (Iverson 1979; Kennett 1992; Kuchling 2003; Legler 1960; Vogt 1980). Pacific Pond Turtles (*Actinemys marmorata*) occur in slow-moving or stagnant aquatic habitats from British Columbia south to northwestern Baja California. The most common techniques used to capture *A. marmorata* have been snorkeling, basking traps, and funnel traps (Bury 1972; Germano and Bury 2001; Reese 1998).

I used capture-recapture methods for estimating population size, structure, and population density of the western pond turtle at Sunol Regional Wilderness, Alameda Co., California, USA. Sites were small to medium-sized (< 400 m^2) artificial stockponds, with a silt and clay substrate, and devoid of emergent vegetation. To optimize my capture and recapture rate, I tested four capture methods: funnel traps, basking traps, hand collecting, and a new technique, baited wires.

Funnel traps measured 0.8 m in length and 0.5 m in width and height. Each trap was made using 2 cm mesh of non-stretch, metallic netting painted dark green. The mouth of the trap was an elliptical funnel decreasing in diameter towards the bait. The mouth of the trap was large enough to allow adult turtles to enter (carapace width of the largest individuals is about 130 mm). Funnel traps were baited with fresh beef attached on a string to the center of the trap.

Basking traps had a rectangular shape and measured 0.8 m in length and 0.6 m in width and depth. A net was held afloat at its perimeter with a PVC pipe of 0.1 m in diameter. Two wood ramps allowed turtles to climb over the PVC pipe and to bask on a platform (0.8 m in length and 0.20 m in width) in the center of the trap.

Hand collecting consisted of walking slowly along the shoreline of the pond. When turtles were observed near the shoreline from a distance of 0.3 m, I used a dipnet to capture individuals before they escaped to deep water.

The baited wires consisted of bait attached to a heavy non-corrosive metallic wire, 0.1–0.2 m long, firmly anchored to a rock or other heavy object along the shoreline of the pond. Yellow vinyl marking flags were attached to the baited wires to locate

TABLE 1. Capture efficiency of three traditional capture techniques for Pacific Pond Turtles, *Actinemys marmorata*, compared to a new technique, baited wires. Data were collected during May 2002, at the Sunol Regional Wilderness, Alameda County, California.

Capture technique	Bait	Number of Traps	Trap days*	Number of Captures	Captures/trap day
Hand	None	None	4	4	1.0
Baited Wires	Beef	4	16	340	21.3
Basking Traps	None	3	12	20	1.7
Funnel Traps	Beef	3	12	5	0.4

*A trap-day consists of one trap set for 3 h between 1000 h and 1600 h.

them from a distance. A bait of fresh stew beef worked very well, even after multiple turtle bites. Sardines or other small fish disintegrated too rapidly in the water and therefore did not work as well. The bait was placed in shallow water usually < 0.25 m from the shoreline. Baited wires were placed around the pond at intervals of 2–5 m and checked every 10 minutes from a distance. When turtles were observed feeding on the bait, they were approached slowly and captured by hand or with a small dipnet. An average of 10 turtles could be caught without changing the bait. My assistant, who had never caught turtles before, tested the baited wires during a three-hour session. Her capture rate was about the same as mine.

The four capture techniques were tested during four days in May and June 2002, with at least seven days between each testing day. These tests were conducted at the beginning of the study in order to find the most effective capture method for my study sites. During each testing day, I exclusively used three basking traps for the first three hours (in about 1.5 h my capture rates dropped to zero). By using only basking traps, I intended to limit basking behavior disturbance that could be associated with the simultaneous use of other trapping techniques. After three hours, I used baited funnel traps and baited wires in addition to basking traps. During this period, I also captured turtles by hand when they were encountered. Three baited funnel traps, three basking traps, and four baited wires were set at haphazard intervals along the banks of a 300 m^2 stockpond known to have a large density of pond turtles. There was no emergent vegetation and the shoreline sloped gradually. The study periods were between 1000 and 1600 h under sunny skies and little wind (< 7 m/sec). Air temperatures were 22–28˚C, and water temperatures at a depth of 0.1 m were 22–27˚C.

The baited wire technique captured more than 20 times the number of turtles captured by the next best technique (Table 1). Using the baited wires, I captured 1–3 turtles every 15 min. This technique created less disturbance than the other methods when turtles were removed.

Turtles caught by hand were mostly hatchlings and small juveniles, which do not feed on beef baits (Bury 1986). All of the hatchlings were captured by hand, either in the water in algae or on land when moving from their nest to the water.

Funnel traps captured few individuals (0.4 per trap day), perhaps because the pond was small and removing turtles and replacing the bait in traps created too much disturbance. Also, turtles appeared to have trouble finding the entrance to the traps.

Basking traps captured turtles during the first part of each daily trapping session (1.7 per trap day), but, in most cases, capture rates dropped to zero during the later half of the trapping session. It appeared that the disturbance caused by removing turtles from the basking traps caused other turtles to avoid the basking traps.

In the proper habitat, baited wires are very efficient, cheap in cost (< US $0.50/wire), and require minimal equipment. Their placement takes very little time. Furthermore, the technique precludes injury to sympatric, threatened or endangered amphibians and reptiles (e.g., California Red-legged Frogs [*Rana draytonii*], California Tiger Salamanders [*Ambystoma californiense*], or Giant Garter Snakes [*Thamnophis gigas*]).

Baited wires work well in ponds with open banks and a low gradient. If the shoreline is too steep, it might be difficult to catch turtles, even with a dipnet. I have never tested the baited wire technique in a stream, but it could also work where the banks are open and the water is shallow.

Acknowledgments.—I thank the East Bay Regional Park District for allowing me to conduct my study at the Sunol Regional Wilderness. I am very grateful to Renée Sittman for her wonderful field assistance. I also thank John Garcia (Garcia and Associates) for providing logistical help. Norman Scott and an anonymous reviewer provided valuable comments on an earlier draft of the manuscript. This study was conducted under the California Department of Fish and Game Scientific Collecting Permit no. 801111-05.

Use of Native Dominant Wood as a New Coverboard Type for Monitoring Eastern Red-backed Salamanders

JEAN-DAVID MOORE
Direction de la recherche forestière, Forêt Québec

2700 rue Einstein, Sainte-Foy, Québec, Canada, G1P 3W8
e-mail: Jean-David.Moore@mrnf.gouv.qc.ca

The Eastern Red-backed Salamander (RBS, *Plethodon cinereus*), probably the most abundant salamander in many forests of eastern North America (Burton and Likens 1975; Conant and Collins 1991; Jaeger 1980), has been widely used as an indicator of forest disturbance in recent years (deMaynadier and Hunter 1998; Harpole and Haas 1999; Moore et al. 2002). Because RBS are ectotherms and lungless, they may be affected by forest canopy loss because of changes in temperature and humidity that result (deMaynadier and Hunter 1998; Harpole and Haas 1999). Furthermore, Welsh and Droege (2001) have proposed the use of plethodontid salamanders (family Plethodontidae) for monitoring biodiversity and ecosystem integrity in North American forests.

The use of artificial coverboards is one of the most popular techniques for monitoring plethodontid salamander populations (Table 1; Fellers and Drost 1994). Coverboards simulate decaying logs or woody debris, under which salamanders can be found (Heatwole 1962; Marsh and Goicochea 2003; Moore et al. 2000). Coverboards are often preferred to other sampling methods, such as pitfall traps and drift fences, night transects, and unit-effort searches of natural cover objects, because they represent a non-disruptive technique, impose little risk of mortality to both salamanders and non-target species, and minimize observer bias and errors (DeGraaf and Yamasaki 1992; Enright et al. 1998; Fellers and Drost 1994; Harpole and Haas 1999). Moreover, coverboards are a time- and cost-effective method for obtaining an index of salamander population size (Enright et al. 1998).

To test the effectiveness of wood from a native dominant tree species to monitor RBS, slices of sugar maple (*Acer saccharum* Marsh.) logs were used as coverboard material in a northern hardwood forest of Québec (Lake Clair Watershed: LCW, Canada). Small boards were used (36 to 42 cm in diameter) because it was easier to transport and install them throughout the watershed. Although several types of wood were used for coverboards in other studies (Table 1), none, to my knowledge, has used wood from a native dominant tree species to monitor salamanders.

The LCW (226 ha, 46°57'N, 71°40'W, elevation: 270 to 390 m) is located approximately 50 km northwest of Québec City, Québec, Canada. The overall vegetation is dominated by deciduous species (83%) with small patches of conifers (17%). The deciduous species consist mainly of sugar maple in association with yellow birch (*Betula alleghaniensis* Britton) and American beech (*Fagus grandifolia* Ehrh.). The coniferous component includes balsam fir (*Abies balsamea* (L.) Mill.), red spruce (*Picea rubens* Sarg.), and white birch (*Betula papyrifera* Marsh.). The soil is a sandy loam of the Ste-Agathe series (Raymond et al. 1976) and is classified as an Orthic Ferro-Humic Podzol according to *The Canadian System of Soil Classification* (Canada Soil Survey Committee 1992). The humus is of mor type, and the main surface deposit is a very acidic and stony till (stone content of 25%, 1–3 m depth) on an underlying granite and syenite bedrock. Average slope is approximately 10%. Mean annual temperature is 3.4°C, and annual precipitation is 1300 mm.

In August 2001, a sugar maple tree with a diameter of 42 cm at breast height was felled. A chainsaw was used to make 104 circular sections of 4 cm thickness from the tree trunk. Boards had a diameter and surface area varying from 36 to 42 cm, and 0.09 to 0.14 m^2, respectively. Thirteen transects were established around the lake, perpendicular to the slope. Sugar maple coverboards were placed in early September 2001 along these transects at distances varying between 0 and 200 m (0, 5, 10, 20, 40, 60, 100, 150, 200 m) from the shore of the lake edge. Boards were allowed to weather for approximately nine months (September to May) prior to sampling. Coverboards were sampled during daylight hours, five times in 2002 and four times in 2003 at approximately six-week intervals from the end of May through mid-October. All boards were checked on a single rainless day (sunny or cloudy). Salamander species were recorded and snout–vent length (SVL) was measured in the field to the nearest 0.1 mm with dial calipers. Salamanders were weighed to the nearest 0.1 g with a 10 g Pesola® spring scale. No attempt was made to sex salamanders. Salamanders were handled in a transparent plastic bag sprayed with lake water. After measurements were taken, salamanders were immediately released at the edge of the coverboard.

Correlation analysis was used to evaluate the relationship between coverboard surface areas and three characteristics of RBS (weight, snout–vent length and number found under each board). Outlier analysis and normality of the data were assessed with residuals. Statistical procedures were performed using SAS v. 8.01 (SAS Institute Inc. 2000).

During the two sampling years, 285 RBS, 23 *Eurycea bislineata* (Two-lined Salamander) and one *Notophthalmus viridescens* (Eastern Newt) were found, for a total of 309 salamanders. Coverboards with solitary salamanders totalled 219, 36 coverboards had 2 salamanders, 3 had 3 and 2 had 4. Eight of the captures were with two-lined salamanders. Such simultaneous captures were also observed in other studies for RBS (Bonin and Bachand 1997; DeGraaf and Yamasaki 1992; Monti et al. 2000), and suggest that RBS are not excluding conspecifics (Monti et al. 2000). These coverboards were used by RBS for reproduction, since egg clusters were occasionally found (~3 egg clusters per year for 104 coverboards).

The encounter rate per boards was 28% and 27% for all salamanders and RBS, respectively. These rates are the highest reported for coverboards in the literature (Table 1). These results confirm the effectiveness of coverboards (Bonin and Bachand 1997; Davis 1997; DeGraaf and Yamasaki 1992; Stewart and Bellis 1970), particularly those used in the present study, for surveying plethondid salamander species. These encounter rates are higher than expected due to the low pH of the upper soil at LCW (pH = 2.8 to 3.6: Houle et al. 1997; Moore, unpubl. data). Previous studies have demonstrated the influence of soil pH on the occurrence of RBS (Wyman 1988; Wyman and Hawksley-Lescault 1987). Red-backed salamanders prefer neutral or basic environments over acidic areas (Mushinsky and Brodie 1975; Vernberg 1955; Wyman

TABLE 1. Studies having used coverboards for monitoring plethodontid salamanders in North America.

and Jancola 1992). Wyman and Hawksley-Lescault (1987) observed that very few individuals of this species were found on forest soils with pH < 3.7. More studies will be needed at the LCW to explain this phenomenon. One explanation for the high encounter rate of RBS under coverboards could be that if woody debris is limited, adding refugia may attract salamanders to an area regardless of other habitat variables (Monti et al. 2000). However, sugar maple decline has occurred for more than a decade at LCW (Duchesne et al. 2003), resulting in a relatively large amount of woody debris on the forest floor. Another explanation could be the younger age of coverboards in the present study (1 to 2 years) when compared to other woody debris. However, a comparison of sampling results from 2002 (137 RBS in five inventories) and 2003 (148 RBS in four inventories) does not support this hypothesis at this time, although longer monitoring will be needed to understand the effect of coverboard maturation and to exclude inter year variation. Other studies also found that the difference between the number of salamanders found under old and new coverboards was not significant (Grant et al. 1992; Monti et al. 2000). One of the most probable explanations for the high encounter rate of RBS

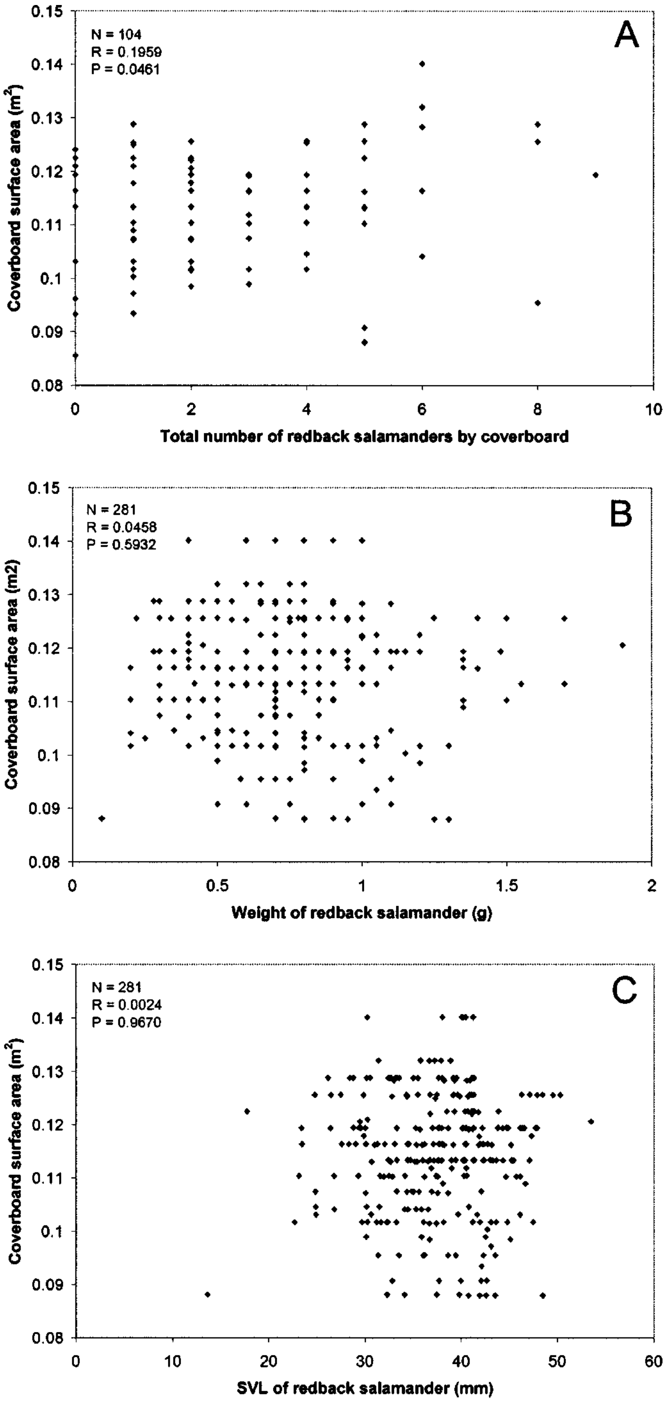

FIG. 1. Regression analysis between coverboard surface area and RBS A) number, B) weight, and C) SVL.

could be the weather prevailing before and at the time of sampling. Coverboard inventories were done, most of the time, during rainless periods (no precipitation the day of the sampling and at least one or two days before), probably forcing salamanders to retreat under coverboards to escape dry conditions. Jaeger (1980) found that the percentage of RBS under logs increased with decreasing rainfall, while simultaneously the percentage of RBS in the leaf litter decreased. This emphasizes the need to monitor RBS during rainless periods so as to maximize coverboard efficiency and, consequently, capture rate.

The relationship between the surface area of coverboards and the number of RBS found under them was significant ($P = 0.0461$; Fig. 1A). However, the weak R value (0.1959) and the relative narrow range of coverboard surface area for each number of salamanders suggests that this parameter was independent of the dimension range of coverboards used at LCW (855 to 1400 cm^2). No relationship was found between the surface area of coverboards and the weight ($R = 0.0458$; $P = 0.5932$) and SVL ($R = 0.0024$; $P = 0.9670$) of RBS during the two-year sampling period (Fig. 1B,C). Similar results were found in Virginia by Faragher and Jaeger (1997) for the size of RBS in spite of a greater range of coverboard sizes (10 to 5000 cm^2) studied. Other studies found, however, that size or weight of RBS was correlated with cover item size (Mathis 1990; Moore et al. 2000) but in these cases, cover size effect was attributed to seasonal influence.

Although no studies have been published that have documented a preference among the salamanders for one type of coverboard over another, it is possible that the wood composition of coverboards (e.g., wood species, chipboard or plywood vs rough-cut) may influence their use by salamanders due to, for example, their wood chemistry and leachate, decomposition rate and moisture retention (Droede et al. 2003). Given the close relationship of salamanders with soil features (Frisbie and Wyman 1991, 1992; Grover 1998; Heatwole 1962; Wyman 1988; Wyman and Hawksley-Lescault 1987), such factors may harm or repel salamanders. The present study was not designed to detect differences among coverboard types. However, the coverboards used at LCW could mitigate this possible phenomenon, given that they were made with *in situ* wood (dominant tree species). Also, in a recent study dealing with potential bias associated with the use of wood coverboard arrays, Marsh and Goicochea (2003) observed that samples from under artificial coverboards contained higher proportions of adult RBS and lower proportions of juveniles and hatchlings than did natural objects. There was, however, no difference in sex ratios or in SVL within stage classes. In this context, more studies will be needed to determine if this new coverboard type accurately indexes the RBS population at LCW.

This study indicates that the use of wood from a native dominant tree species to make coverboards is an efficient tool for surveying and monitoring plethodontid salamanders. Preparation can be done *in situ*, reducing transport and cost. The results suggest that, under a relatively narrow range (0.09 to 0.14 m^2), variability in coverboard surface area has no effect on salamander encounter rate, weight and snout-vent length. More studies will be needed at LCW to explain the high encounter rate of RBS in this acidic habitat.

Acknowledgments.—I am grateful to Jean Gagné, Rosalbina Gomez-Segura, Andrée-Anne Marmette, Annie Quimper and Sylvie Tremblay for their help in salamander sampling. I also thank Denis Hotte for his technical support and the two anonymous reviewers for their constructive comments.

In 2003, a long-term program to monitor pond breeding amphibians at Cape Cod National Seashore, Barnstable County, Massachusetts (Paton et al. 2003) was initiated. One aspect of this program involves the use of egg mass counts for monitoring long-term population trends of the vernal pond breeding wood frog (*Rana sylvatica*) and spotted salamander (*Ambystoma maculatum*). Crouch and Paton (2000) found that counts of egg masses in ponds were the most cost-effective means of monitoring wood frog populations. Egg mass counts may also be used to estimate abundance and monitor populations of spotted salamanders (Brodman 1995, 2002; Egan and Paton 2004; Jung 2002; Petranka et al. 2003).

While there is a general agreement that egg mass counts are an effective and accurate way to estimate abundance and monitor populations of spotted salamanders (See Shoop 1974 for a contrary opinion), researchers have employed a number of approaches. Brodman (1995, 2002) used random transects across a pond to estimate egg mass density. Others have attempted to count all the egg masses present, based on either a single count of egg masses (e.g., Rowe and Dunson 1993) or multiple counts. One method of multiple counts involves marking egg masses or groups of egg masses to generate a cumulative total (Egan and Paton 2004), hereafter called the locus method (Paton et al. 2003). A second approach to multiple counts is to count (but not mark) all egg masses in the pond on a series of sample dates spanning the breeding season, and use the maximum count as the measure of abundance (Albers and Prouty 1987; Petranka et al. 2003; Petranka et al. 2004). A third, more recently employed multiple count method is the dependent double observer approach. This applies the double observer method of Cook and Jacobson (1979) to estimate the number of egg masses present on a series of counts based on their probability of detection. It then uses the maximum estimate as the measure of abundance (Grant et al. 2005). As with the other multiple count methods, this technique allows better estimates of the maximum number of spotted salamander females breeding at a site than a single count. Including additional observers allows less biased estimates of this variable (Nichols et al. 2000).

In 2003, we compared the maximum count and locus methods for counting egg masses of spotted salamanders in breeding ponds. The maximum count method involves carefully and systematically counting all the egg masses found in a breeding pond on a series of dates during the breeding season. The largest of these counts is then used as the measure of egg mass abundance for that pond that year. The locus method (Paton et al. 2003) is based on the fact that egg masses of wood frog and spotted salamander are often clustered together in a group or locus. The locus method involves counting the number of egg masses in a group (locus), and identifying and marking each locus with flagging. Single, isolated egg masses are also treated as a locus and marked. Each locus and the number of egg masses it contains is recorded. On a subsequent visit, each locus is recounted and the number of egg masses present recorded. Differences in the number of egg masses recorded in a locus from one count to the next may be due to predation, displacement (dislodging an egg mass from vegetation), the laying of additional egg masses, overcounting, or undercounting egg masses that were present during a survey. New (unmarked) loci encountered are also marked, counted, and recorded during subsequent surveys. These new loci may also represent egg masses deposited after the previous visit, or egg masses that were present during the last survey but overlooked. After repeat visits, the maximum count for each individual locus is selected and all loci in a pond summed, providing a total count of the eggs masses deposited in that pond.

Methods.—In spring 2003 we conducted two rounds of spotted salamander egg mass counts at 18 ponds in Cape Cod National Seashore. The first count was conducted between 14 April 2003 and 21 April 2003, and the second, between 28 April 2003 and 5 May 2003. This is generally the period of greatest egg mass abundance. Since data collected on a given day as part of the locus method can also be treated as a count in the maximum count method, we used these data to compare the results obtained by these two different methods. For each pond, the highest of the two daily counts was the maximum count, whereas the locus count was obtained by taking the highest of the two counts of each locus and summing for all the loci in a pond.

Results.—The maximum daily count method underestimated the locus method, on average by 2.7% (range 0–12%; Table 1). Maximum count values were significantly less than those obtained by the locus method (paired t-test $t = -3.46$; $df = 17$; $P = 0.003$), but were highly correlated with them ($R = 0.9996$; $P < 0.000000$; $N = 18$). The mean field time for data collection using the maximum count method was 29 minutes/pond and for the locus method it was 80 minutes/pond. Thus, relative to the locus method, the maximum count method systematically underestimated the number of egg masses present, on average by 2.7%, required 36% the field time, and provided highly correlated results.

Discussion.—Implementation of the locus method was problematic. Determining what constituted a “locus” was often difficult. While many egg masses form discrete loci, many egg masses are also laid singly or in small groups. Egg masses may be spread over a large area rather than concentrated in a small one. When single egg masses were near a larger group of masses, we had to decide whether to consider it a separate locus or group it with a larger neighboring locus. Moreover, since egg mass deposition takes place over the course of a few weeks, seemingly distinct loci early in the season become less so as the space in between them fills in with additional egg masses. To deal with this problem, we had to delineate boundaries between what initially were distinct loci with flagging, labeled to indicate which locus it defined. Using this method, we could be sure we were counting the same locus as in the prior sample and could determine whether egg masses were added or lost. However, defining, labeling, delineating, and recording each locus was a very time consuming process. In addition, the locus method took more time to enter and tabulate

TABLE 1. Comparison of maximum count versus locus method values for spotted salamander egg masses in 2003.

Pond	2003 Max Count	2003 Locus	Difference	% Deviation
E02	50	51	1	2%
E03	38	41	3	7%
E04	633	639	6	1%

W15	64	66	2	3%
W18	44	46	2	4%
Total	4964	5103	139	2.7%

data.

The advantage of the locus method is that, by tracking the number of egg masses in a locus over sampling visits, egg masses once counted but then lost to predation or displaced during counting are still counted, as are newly deposited egg masses. This provides a more complete count of the total number of egg masses deposited. In contrast, maximum counts do not allow for tracking the disappearance of older or the appearance of newer egg masses, and may underestimate the total number of egg masses laid. While we found this to be true, egg mass counts based on the maximum count method provided nearly identical data as the locus method, but in a more time efficient and economical fashion. Increasing effort 276% to detect, on average, 2.7% more egg masses, is not worth the additional effort.

Of these two methods, we would recommend use of the maximum count method, provided that at least three counts are conducted during the appropriate time period. On Cape Cod, we conduct three counts, with the first occurring the last week of March–first week of April, the second in mid-April, and the third in the last week of April–first week of May. This ensures that regardless of whether it is an "early" or "late" spring, counts will occur during the time of peak egg mass presence. Elsewhere, sampling would need to be adjusted for local phenology.

While our results indicate that the maximum count method provides data comparable to the locus method for less effort, neither method addresses the issue of egg mass detectability raised by (Grant et al. 2005). Shoop (1974) felt that egg mass counts underestimated the numbers of spawning females due to the inablity to detect egg masses in deep (> 2 m), turbid water. Egan and Paton (2004) also noted that deeper (>1.5 m) sections of ponds are hard to survey.

The dependent double observer method of egg mass counts (Grant et al. 2005) attempts to account for differences in the detectability of egg masses due to such factors as observers, sites, vegetation, pond size and depth. In its implementation, the primary observer counts egg masses in groups out loud, and the secondary observer records the primary observer's counts and silently records any egg masses the primary observer missed (Jung 2002). Halfway around the pond, the observers switch roles. In our experience with this method in vernal ponds at Cape Cod National Seashore, it is not always feasible in practice. A fundamental assumption of this method is that the sighting ability of an observer does not change as they shift from the role of primary to secondary observer (Southwell 1996). But, suspension of silt, differences in the visibility of egg masses to the observers due to differences in glare and view angle, and the fact that the primary observer often must handle egg masses below the water's surface to count them frequently makes it impossible for the secondary observer to follow along in the count with the primary observer. Thus the secondary observer is often less able to detect egg masses than the primary, resulting in a systematic undercount by the secondary observer and a violation of the above assumption.

While we concur with Grant et al. (2005) on the desirability of modeling detectability to obtain unbiased estimates of the number of spotted salamander egg masses in a pond, our experiences suggest that it may not always be feasible. A more optimal method to assess detectability of egg masses has not yet been developed. In situations where conditions lead to violation of the assumptions of the dependent double observer method, the only reasonable recourse to estimating egg mass abundance, particularly when more than a few ponds are being monitored, seems to be single observer counts, such as the maximum count method described above. We acknowledge that the maximum count method is less than perfect, but believe it provides a meaningful index of spotted salamander breeding effort (e.g., see Petranka et al. 2004) and represents the best currently available compromise among the competing factors of accuracy and precision, ease and economy of implementation in a long term monitoring program, and minimizing monitoring impacts to pond vegetation and wildlife.

Acknowledgments.—Matthew Schult and James Lyon assisted in the field work. E. Grant, R.Jung, J. Nichols, and P. Paton provided valuable discussion and/or comments on an earlier draft of this note. This work was conducted as part of the Cape Cod National Seashore Prototype Monitoring Program.

A Novel Arboreal Pipe-Trap Designed to Capture the Gray Treefrog (*Hyla versicolor*)

JARRETT R. JOHNSON
Division of Biological Sciences,University of Missouri
Columbia, Missouri 65211, USA
e-mail: jrj886@mizzou.edu

Drift fences with pitfall traps are a common and effective method of censusing amphibian populations (Dole 1971; Gibbons and Bennett 1974; Gibbons and Semlitsch 1982; Shoop 1965). However, drift fence arrays are ineffective for capturing hylid frogs because of their ability to climb vertical surfaces (Dodd 1991; Gibbons and Bennett 1974). The difficulty of capturing treefrogs using drift fences has led to the development of alternative sampling techniques for hylid frogs including open-ended polyvinyl chloride (PVC) pipes, elevated inverted tin cans, and modified drift fences (Boughton et al. 2000; Goin and Goin 1957; Moulton et al. 1996; Murphy 1993). Currently, the most widely used of these methods consists of constructing artificial refugia from PVC pipe. Several studies have found that varying pipe-trap designs and configurations lead to differences in species composition and size classes of captured individuals (Bartareau 2004; Boughton et al. 2000; Moulton et al. 1996), suggesting that no single pipe-trap design is appropriate for all species in all locations. Here I report on the design and effectiveness of a novel pipe-trap designed to simulate natural arboreal retreats and capture the gray treefrog (*Hyla versicolor*).

The pipe-traps used in this study consisted of 60 cm long sections of 3.8 cm inside diameter black acrylonitrile butadiene styrene (ABS) pipe (Fig. 1). A 10 cm upper and 15 cm lower section of 5.0 cm inside diameter black ABS pipe were attached to trees with bungee cord and wire (Fig. 2). The smaller diameter pipe slid freely up and down during monitoring (Fig. 3), and the flexibility of the bungee cord allowed the 5.0 cm diameter sections of pipe to twist during monitoring, while remaining at the correct position on the tree. Utility wire was used to increase tension of the bungee cord on the upper and lower sections of the trap (Fig. 2) and to provide a pivot point during monitoring (Fig. 3B). Traps were sealed at the bottom with 5.0 cm diameter black ABS caps to allow for rainwater to fill the lower sheath of the 5.0 cm diameter pipe (Fig. 1). Water levels remained constant within the pipe-trap because the inside pipe sat loosely within the bottom capped portion, and excess rainwater flowed out. Frogs were able to enter and leave the pipe-trap freely at the upper opening (Fig. 1).

The pipe-trap design outlined here is similar to some PVC pipe designs evaluated by Boughton et al. (2000). However, I modified their designs in three ways. First, black ABS pipe was used rather than white PVC pipe to provide more realistic (i.e., dark) refugia sites (Lohoefener and Wolfe 1984). Other possible advantages of the dark material may include warmer internal temperatures and greater camouflage from potential predators. ABS pipe is typically used for residential plumbing applications and is similar to the polyvinyl chloride (PVC) piping used in previous studies of artificial arboreal refuge use by treefrogs. Second, I eliminated

the need to nail pipe-traps directly onto trees, which avoids damage to trees and can be an important consideration in old growth forests, or on public lands that discourage the permanent disturbance of habitat. Lastly, this pipe-trap design maintains a constant

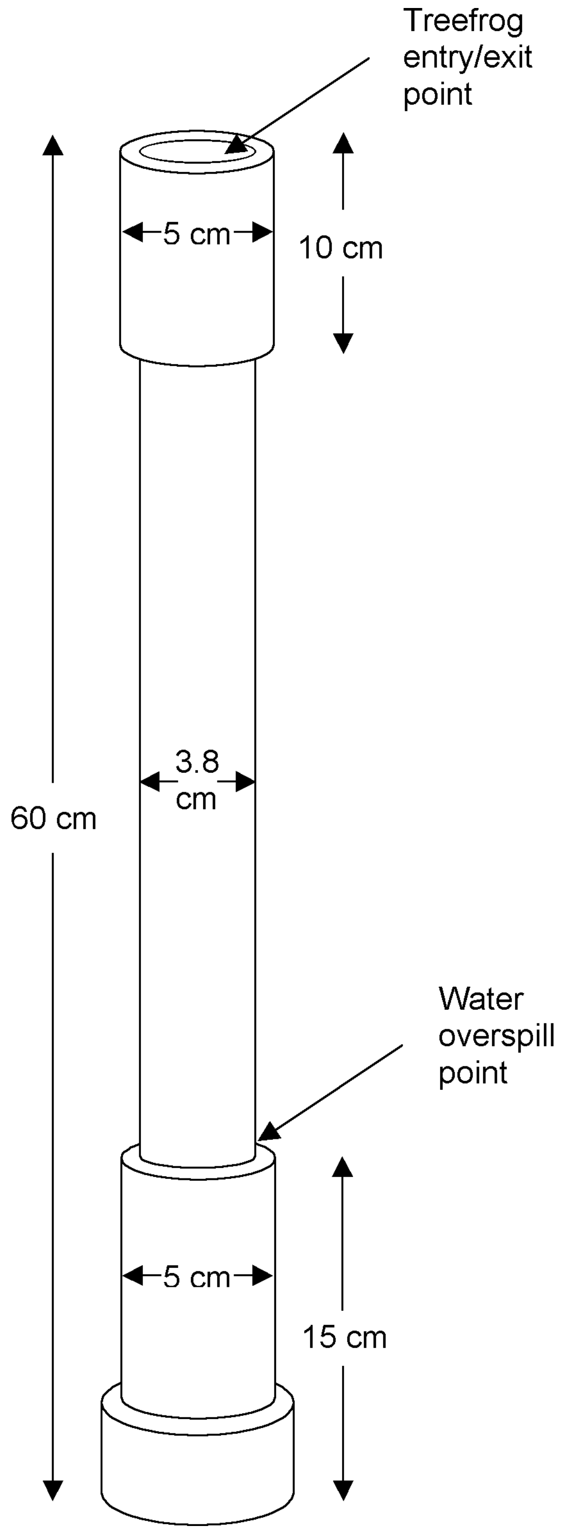

FIG. 1. Pipe-trap design. The smaller diameter inside pipe slides freely through the larger diameter top sheath and rests inside the capped bottom portion of large diameter pipe. The gap between the small and large diameter pipe maintains water level at a constant depth.

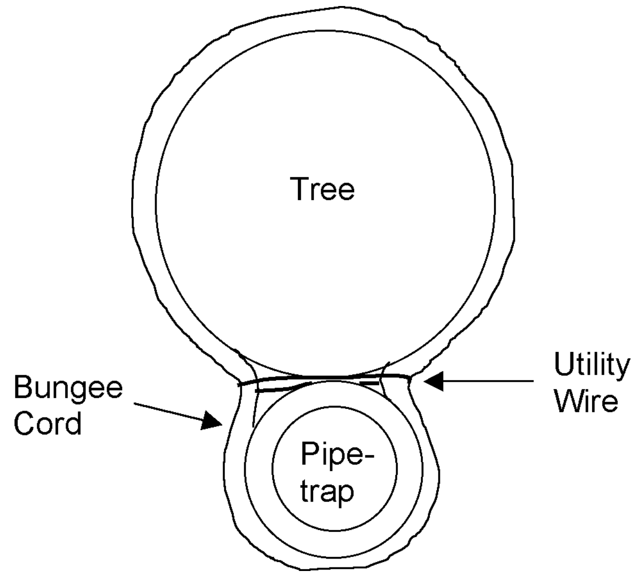

FIG. 2. Top view of a pipe-trap attached to a tree. Not shown is a second bungee cord and utility wire attachment on the bottom segment of the 5 cm diameter pipe.

water depth within the pipe-trap. If frogs are attracted to pipe-traps because of the water they contain, it is important to standardize water level among traps.

The pipe-trap refugia described in this report were constructed for an ongoing study of gray treefrog dispersal distances and terrestrial habitat requirements. To date, pipe-traps have been monitored during two fall emigrations as frogs move towards overwintering sites, two spring immigrations as frogs move towards breeding sites, and two summer breeding seasons (Table 1). Here I present data regarding the effectiveness of these traps for capturing gray treefrogs in a midwestern U.S. deciduous forest.

During the fall of 2002 and the spring of 2003, I placed 28 pipe traps at two adjacent gray treefrog breeding sites located within the Thomas Baskett Wildlife Research Area near Ashland, Boone County, Missouri. The pipe-traps were placed with the upper opening 3 m above ground on large diameter deciduous trees (mean DBH 21.8 cm) and arranged at fixed distances from breeding ponds along four transects. Each transect extended from the breeding sites 200 m into secondary growth (~100 yr) oak/hickory (*Quercus* spp./*Carya* spp.) forest with sugar maple (*Acer saccharum*) understory. During the summer of 2003, the existing transects received an additional pipe-trap at each distance and three paired transects were added to a third gray treefrog breeding site, for a total of 98 pipe-traps in seven paired transects extending 200 m from three breeding ponds into the adjacent forest. An additional pipe-trap was placed 200 m from each of the two breeding sites for a grand total of 100 pipe-traps. During monitoring, pipe-traps were checked during daylight hours for the presence of treefrogs. Frogs were extracted from the pipes by forcing a sponge through one end until the frog could be reached at the opposite end (Boughton et al. 2000; Fig. 3C). Individuals were sexed, given unique toe-clip identifications and snout–vent length (SVL) was measured with a plastic ruler. After processing, frogs were returned to the pipes and placed back on the tree.

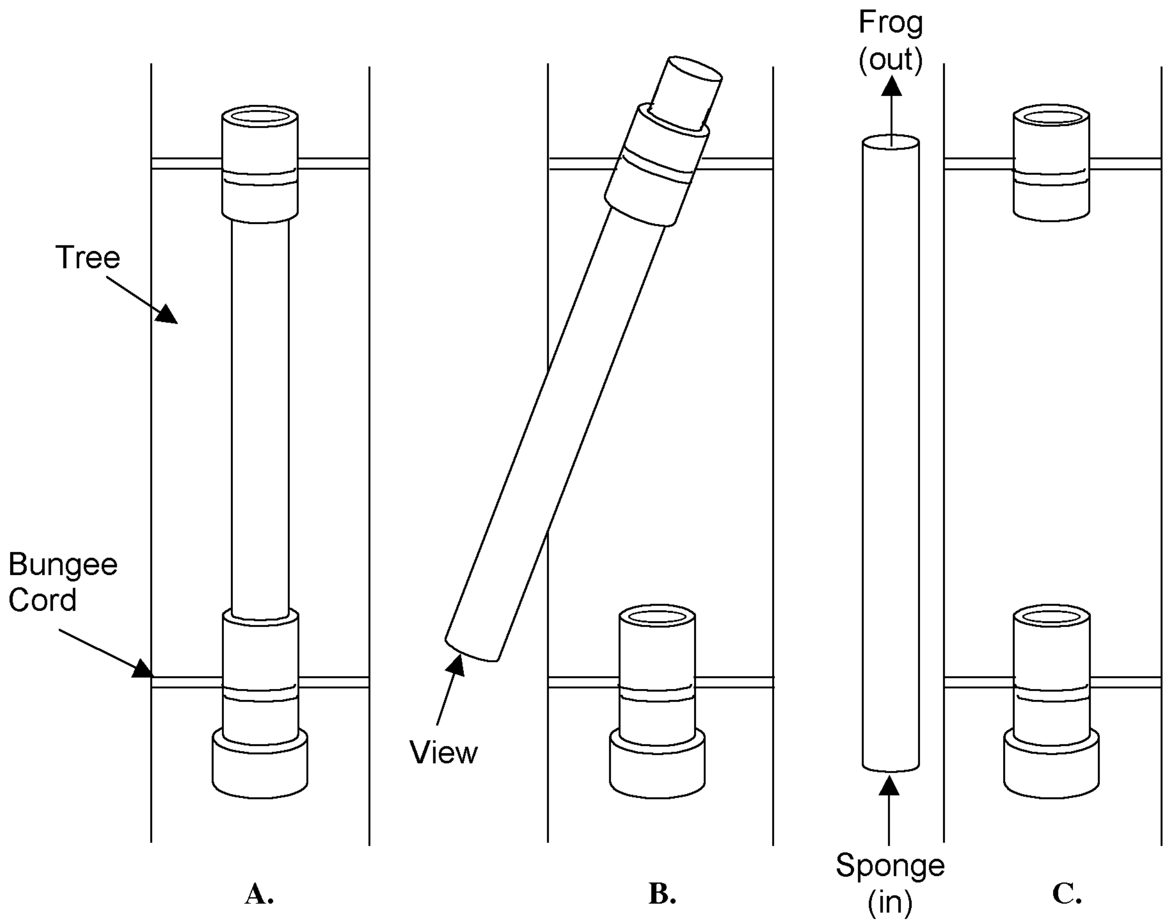

FIG. 3. Overview of pipe-trap monitoring procedure. A. Normal pipe-trap position. B. Inside pipe is slid upwards and top sheath twists on bungee cord so the observer can detect frogs from below. C. If a frog is present, the inside pipe is removed and the frog is extracted.

In total, pipe-traps captured 111 Gray Treefrogs (60 males, 36 females, and 15 juveniles) a total of 565 times (Table 1). The size range was 17–56 mm SVL, which encompasses the entire range of adult gray treefrog lengths (Conant and Collins 1998). The SVL data indicate that these pipes are capable of capturing all size classes of *Hyla versicolor*; however, without size frequency distribution data for the population, it remains unclear if these data display a bias in capture rates generated by the internal pipe diameter (see Bartareau 2004; Martin et al. 2003).

Other vertebrate species captured in the traps include one adult Spring Peeper (*Pseudacris crucifer*), one adult Five-lined Skink (*Eumeces fasciatus*), eight mice (*Peromyscus sp.*), and seven flying squirrels (*Glaucomys volans*). I observed no amphibian mortality within the pipes, however 12 of the 15 mammals encountered were dead. Prior studies using pipe-trap refugia for monitoring amphibians have not reported mammalian mortality. Use of this pipe-trap design might not be appropriate in areas in which incidental small mammal mortality is of concern, unless the open end of the pipe-trap can be modified to reduce the frequency of mammalian intruders without affecting treefrog access.

Previous studies using PVC pipe refugia have been conducted primarily in the southeastern U.S. to monitor other species of hylids (e.g., *H. avivoca, H. cinerea, H. femoralis, H. gratiosa*). These artificial refugia studies have been successful in capturing treefrogs

TABLE 1. Summary of monitoring sessions and captures.

Season	# of pipe-traps	Monitoring period	# of days monitored	# of recaptures	# of males	# of females	# of juveniles
Fall 2002	28	30 Sept. to 15 Oct.	4	7	3	1	1
Spring 2003	28	17 Apr. to 05 May	10	20	4	1	1
Summer 2003	100	17 June to 08 July	11	20	3	10	2
Fall 2003	100	11 July to 22 Oct.	42	290	31	16	21
Spring 2004	100	09 April to 14 May	18	83	18	13	14
Summer 2004	100	18 May to 11 July	28	145	29	17	8

in pipe-traps inserted upright into the ground, placed open-ended or capped at varying heights on trees, and in "T" configurations (see Bartareau 2004; Boughton et al. 2000; Moulton et al. 1996). However, in more northerly locations (Michigan; J. Ball, pers. comm.; New York, Tregger 2004) similar pipe-trap designs have not succeeded in capturing large numbers of treefrogs. The large number of captures reported in this study indicate that this new pipe-trap design may be more appropriate than previous designs for sampling populations of hylid frogs in areas outside of the southeastern U.S. Additional data regarding the factors that drive the use of artificial refugia would be beneficial to the development of pipe-traps designed to optimize captures of particular species in specific locations. For example, the height at which a pipe-trap is placed, the internal diameter and the depth of water retained within the pipe-trap could easily be adjusted to fit the specific requirements of the hylid species under investigation. While the use of pipe-trap refugia to generate estimates of treefrog density or abundance may be complicated by biases of pipe diameter and design configuration, artificial pipe-trap refugia may be especially useful for delineation of terrestrial core habitat used by hylid frogs during both the breeding and non-breeding seasons when traditional methods of capturing amphibians are inadequate.

Acknowledgments.—I thank D. Johnson and G. Johnson for helpful discussions regarding trap design, and T. Rittenhouse, R. Semlitsch, and D. Shephard for insightful comments on the manuscript. Thanks also to R. Mahan and J. Haynes for assistance with fieldwork, and to J. Millspaugh for access to field sites.

A New Method of Temporarily Marking Lizards

MICHELE A. JOHNSON
Department of Biology, Washington University
St. Louis, Missouri 63130, USA
e-mail: mjohnson@biology2.wustl.edu

Labeling individual animals with unique and distinct markers is necessary in many ecological studies, including population density assessments, estimates of home range or territory areas, and behavioral observations. Researchers have developed many techniques for identifying individuals, but few allow convenient field identification of individuals from a distance. The ability to distinguish among individuals without repeatedly disturbing them is especially important in studies of behavioral ecology where the goal is to determine natural patterns of behavior. The most appropriate marking techniques for these studies are therefore quickly and easily implemented, clearly distinguishable from a distance, and not harmful to the marked individual (Murray and Fuller 2000; Nietfeld et al. 1994). I have developed a new method for temporarily marking small lizards that meets these criteria.

Individually marking reptiles presents a special challenge for field workers in that reptiles frequently shed their skin and with it any external markers. The bead-tagging method of Fisher and Muth (1989) avoids this problem by sewing unique combinations of beads into the most proximal region of a lizard's tail muscle. This is a permanent marker that works well for lizards that have a snout-vent length (SVL) of greater than 40–45 mm, but one that is difficult and often impossible to use for smaller lizards and for those with very slender tails. Other common methods of marking lizards have shortcomings as well. Many researchers use toe-clipping to distinguish among individuals (Ferner 1979). However, there are several problems with using this method in short-term behavioral studies. First, it may take a substantial amount of time for a toe-clipped lizard to recover from the injury caused by the clipping, which may further inhibit normal behavioral and movement patterns. Second, lizards sometimes naturally lose toe joints (Hudson 1996; Middelburg and Strijbosch 1988), which can make identifications difficult. Finally, toe clips cannot easily be seen without handling the animal. Other researchers have used non-toxic paint on the dorsum or colored acrylic polymers inserted under the skin, but these are also difficult to administer and distinguish on small lizards. For studies that can be completed in less than the average interval between natural sheddings of the species, I recommend the use of queen bee marking kits for smaller lizards. These kits, available from The Bee Works of Orillia, Canada (www.beeworks.com) for US $17.50 each, contain cardboard dots in five colors (white, blue, yellow, green, and orange) numbered 1–99 in each color. Each kit also includes phial glue and an applicator for adhering the dots to the animal.

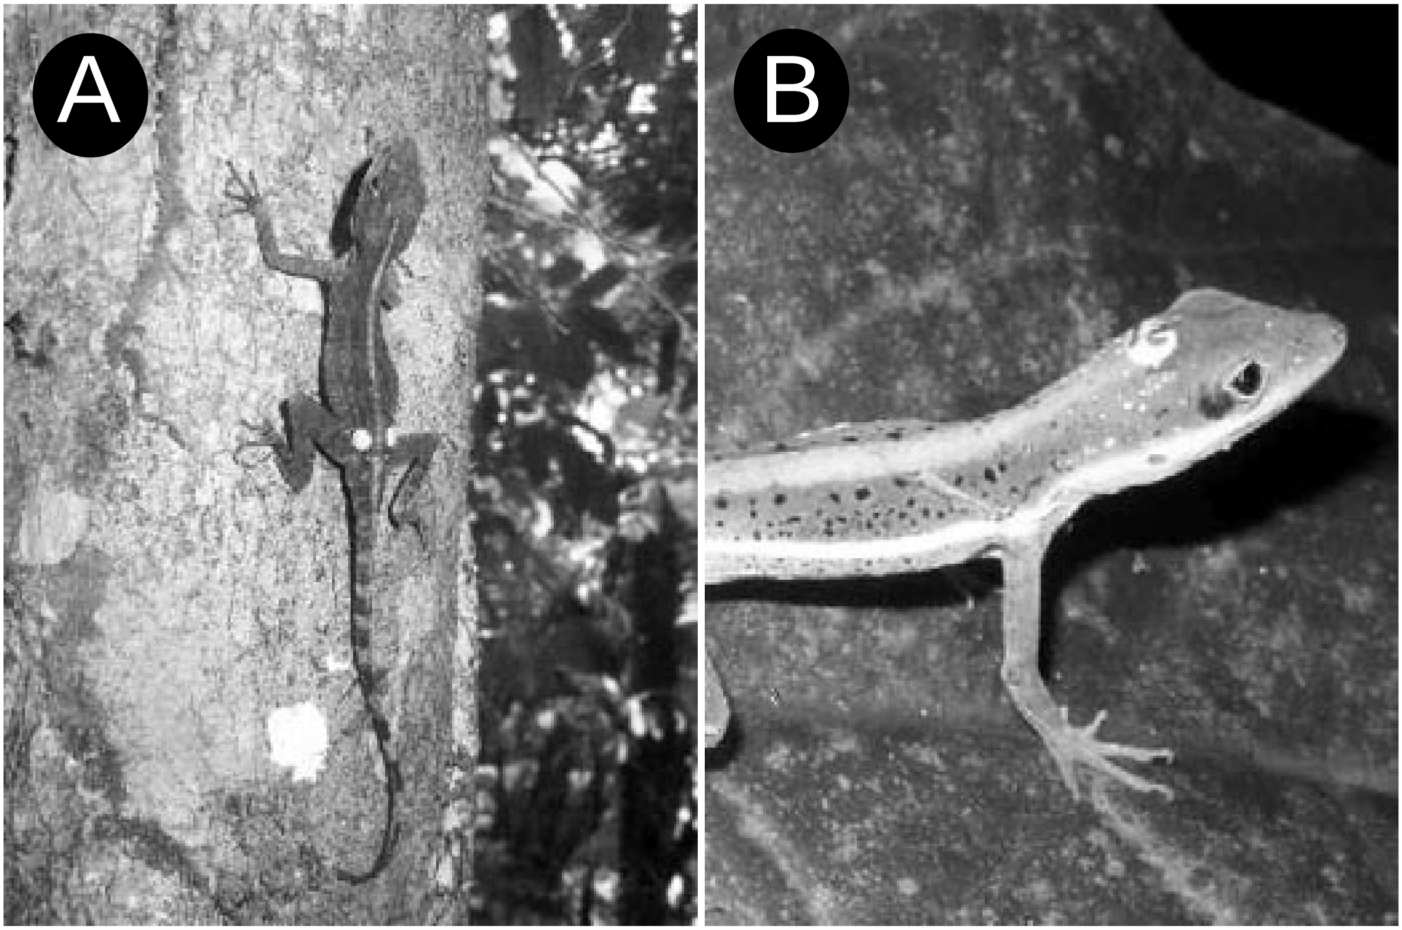

FIG. 1. A) Female *Anolis gundlachi* with two bee tags attached to its lower dorsum. B) Female *Anolis krugi* with bee tag (numbered 21) attached to its head.

We have used bee tags for marking four species of diurnal lizards: *Anolis cristatellus*, *A. gundlachi*, *A. krugi*, and *Sceloporus undulatus*. These four species have different habitat requirements and different scale types, and bee tags have proven to work well for each. *Anolis gundlachi* and *A. krugi* occur in the montane rainforests of Puerto Rico (Rand 1964; Schoener and Schoener 1971), *A. cristatellus* occurs in lowland dry forests and disturbed areas in Puerto Rico (Rand 1964; Schoener and Schoener 1971), and *S. undulatus* is found in North American woodland areas and glades (Stebbins 1954). During our behavioral studies of these species, we found that bee tags were dependable markers for approximately three weeks in the natural habitats of these species. We marked males and large females with the bead-tagging method described above (Fisher and Muth 1989), and smaller females and juveniles with bee tags. Bee tags are remarkably easy to attach; after catching a lizard we handled it for approximately two minutes to measure its SVL, take a small tissue sample from its tail, attach a bee tag combination, and allow the glue to dry. In contrast, almost twice that time was needed to attach a bead tag. Another primary advantage of the bee tag technique is its flexibility; the dots can be glued on almost any part of the dorsal surface of the lizard (Fig. 1). In our studies, we glued 2-3 bee tags on the head, the upper dorsum, or the lower dorsum of the lizards using the colors, numbers, and location of the tags to identify individuals. While the colors and position of the tags are often visible with the naked eye, close-focus binoculars were needed to read the numbers on the tags. When a tag was occasionally missing from a lizard, we were almost always able to identify the individual by the remaining tags on that individual, or by a process of elimination in which other lizards of known identification were ruled out.

Marking lizards with bee tags provided short-term results comparable to those of the bead tagging technique (Fisher and Muth 1989). Of the 166 lizards of the four species we have marked using the bee tag method, we were able to conduct behavioral observations on 141, or 85%, in a three-week period. Likewise, of the 75 lizards marked with permanent bead tags for the same studies, we were able to observe 66, or 88%. It therefore appears that these two methods have similar "success" rates. There are many reasons we may fail to repeatedly observe a lizard other than loss of its tags, including death by predation or disease. It is also logical to assume that some lizards may be captured in a rare foray from their normal home range into the study area. However, we did observe one lizard (a female *A. krugi*) shed its entire skin and eat its dots immediately after being marked with bee tags, and the dots of one female *A. cristatellus* were found in its feces. These occurrences appear to be rare in the field, but when *Anolis* lizards were placed in the animal care facility at Washington University almost every individual shed and ate its bee tags.

In many circumstances, marking small lizards with queen bee marking kits is preferable to other marking techniques, as it is

inexpensive, relatively non-intrusive, and an easily visible way to identify particular individuals. The technique is also useful for larger lizards when temporary highly visible markers are preferred to permanent ones, particularly in studies in which the researcher wishes to avoid disturbing the focal individuals as much as possible.

Acknowledgments.—Many thanks to J. Chase for the original suggestion of bee tags for use in my behavioral studies, and to R. Kirby and S. Wang for their enthusiastic assistance in the field. J. Kolbe, J. Losos, K. McIntyre, and N. Calder provided helpful comments on an earlier draft of this manuscript. This work was supported by a grant from the National Science Foundation (DEB 9982736).

Many herpetologists are using cell culture to answer questions ranging from cell and tissue function to studies of the aging process. This paper reports a culture technique improved from that of Rund et al. (1998), especially a method of concentrating cells such as melanomacrophages (MMs). We became interested in these cells with the discovery that they formed aggregations in spleen, liver, and other organs in mud turtles, *Kinosternon flavescens*, and that these aggregations increase in number and size with turtle age (Christiansen et al. 1996). Aggregations of MMs have been reported in fishes (Aguis 1985), amphibians (Sichel et al. 1997), and some reptiles (Duncker 1968) among others. The basics of our methods were similar to those of Clark and Karzon (1967), Clark et al. (1970), and Koment and Haines (1982). Ulsh et al. (2000) used autologous turtle serum instead of fetal bovine serum to facilitate culture of reptilian lymphocytes.

In our studies of the advantages these cells provide turtles in low temperature environments (Johnson et al. 1999), we observed that our cultures became overrun with fibroblast-like cells. Our need to obtain nearly pure cultures of MMs for this study as well as our need for nearly pure fibroblast-like cell cultures for our current studies of aging and the aging process in reptiles, necessitated development of the purification techniques we report here. In addition, our MM cultures have provided evidence for a potential reason for the hepatic aggregations.

Culture Technique.—Liver and spleen from Western Painted Turtles (*Chrysemys picta bellii*) were used for preparation of MMs and these tissues along with skin and lung provided cells for fibroblast cultures. The turtles were collected and sacrificed under scientific collecting permit SC255 0101 and others issued to JLC by procedures approved by the Drake University Animal Care Committee as reported in Rund et al. (1998). Approximately 10 mm cubes of tissue were placed in RPMI-1640 (Sigma-Aldrich, Inc., St Louis, Missouri) containing penicillin, streptomycin, and neomycin (100 IU/ml: 100 mg/ml; 200 mg/ml, respectively, all from Sigma-Aldrich, Inc.). Tissues were rinsed three times in 40 ml RPMI-1640 with antibiotics to remove clotted blood and debris. Washed tissues were transferred to petri dishes and crossed scalpels were used to divide them into 2–3 mm cubes. The cubes of friable organs were pushed through a 1.0 mm stainless steel screen with a spoonula but skin was shredded further with crossed scalpels. The tissue fragments, cell aggregates, and individual cells

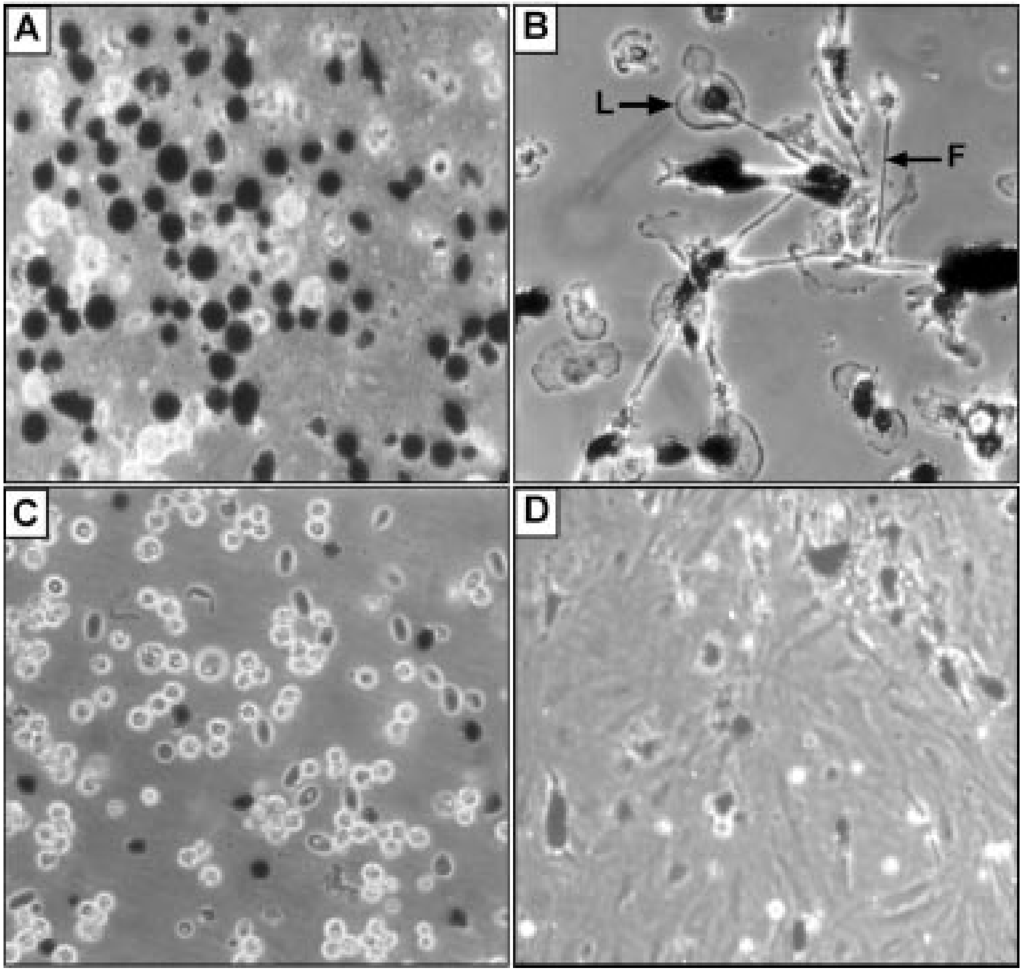

FIG. 1. Purification of reptilian cells for culture by selective trypsinization and differential settling. Initial plates (A and C) have app. 30,000 cells per plate. A = Selectively trypsonized and settled cells one hour post plating showing nearly pure culture of melanomacrophages (cells with black pigment). B = Same culture 25 days post plating. L indicates feeding lamellapodia; F indicates one of many forms of filapodia forming a network. C = Cells prepared by standard technique (Rund et.al. 1998) one hour post plating showing few melanomacrophages and abundant other cells. D = Same plate 15 days post plating showing culture overrun with fibroblast-like cells. We have used selective trypsinization to prepare nearly pure fibroblast cultures as well as melanomacrophage cultures. Blood cells do not attach and are eliminated when the cultures are fed.

were collected in complete medium (CM), RPMI-1640 with 7.5% fetal bovine serum (Gibco Inc. Grand Island, New York) and penicillin, streptomycin, and neomycin at half the concentrations used above. The cells and aggregates were allowed to settle for 8 min through a 40 ml column of CM in a sterile centrifuge tube. The pellet was collected, trunulated (repeatedly pulled in and out of a 10 ml pipette) in fresh CM to resuspend and separate the cells, and the cells were resettled as before. This procedure removed much of the cellular debris. The pellet was then resuspended in CM and transferred to ten 75cm^2 T flasks as described in Rund et al. (1998). Individual viable cells and aggregates of either MMs or fibroblasts or both attached to the substratum and spread within 3–5 days post-plating during incubation at 29˚C in a humidified incubator operating at 5% CO_2. CM was decanted and replaced with fresh CM after one week. Additional cultures were started from the decantates that contained viable cells and aggregates that had not yet fully attached. These cells and aggregates were centrifuged, resuspended in CM, and then vigorously trunulated to further separate cells before depositing cells in T flasks. MMs and other cells including many fat droplet-bearing cells were obtained by this procedure and their viability was demonstrated by their ability to attach to the flask substratum and spread.

Approximately 28 days after establishment of these primary cultures containing mixtures of cells, MMs were collected by selective trypsinization. Unattached cells such as RBCs and fragments of tissue were removed by gentle shaking and decantation. A warm 1:5 dilution of 0.25% trypsin-EDTA (Sigma-Aldrich, Inc.) in sterile PBS (10 mM phosphate buffer, pH 7.2, 137 mM NaCl) was added to the flasks and incubated for 5–7 minutes. Most fibroblasts, fat droplet-bearing cells, and hepatocytes rounded up and detached from the substrate with gentile shaking. These could be cultured in other flasks if desired. A few fibroblasts always remained but this procedure could be repeated when relatively pure MM cultures were desired. The MMs rounded and detached after approximately 15 minutes or with the addition of fresh trypsin-EDTA. The enriched MM fraction was collected by centrifugation for three minutes at 1000 x g and cultured at plating densities of 0.5–3.0 x 10^3 cells/cm^2 in T flasks. The enriched MM fraction consisted mostly of MMs with some debris and a few hepatocytes (Fig. 1A). Cells were maintained at 29˚C in CM with media replacement at weekly intervals. Cultures were selectively trypsinized if overgrowth by fibroblasts occurred. Overgrowth of MMs did not occur because these apparently end-stage, differentiated cells rarely, if ever, divided in culture. Selective trypsinization and settling as described herein, typically resulted in cultures that were greater than 90% MMs based upon microscopic determinations of melanin in attached and spreading cells (Fig. 1B). These cultures could be maintained free of fibroblast overgrowth for many weeks depending on the burden of fibroblasts in the selectively trypsinized cell fraction.

Fibroblast and other cells in preparations that were not selectively trypsinized (Fig. 1C) would grow into colonies and further multiplied to form confluent cultures of mostly fibroblasts in 10–20 days depending upon plating densities, species, age of the culture (number of times the culture had been passaged), and age of the animal from which the culture was obtained (Fig. 1D).

MM Aggregations.—Melanomacrophages tended to adhere to each other. The MM centers in the liver and spleen were resistant to trypsinization and disaggregation and clumps of MMs were lost during culturing as they did not bind sufficiently well to the plastic substratum to resist decantation during media replacements. Upon selective trypsinization, MMs tended to reaggregate to form collections of 2–6 cells that appear as the larger spherical clusters in Fig 1A. These would often settle to form clusters of MMs (Fig. 1B). MMs that had aggregated or individual MMs that otherwise found themselves in relatively close proximity to each other in culture, used a variety of cellular processes to form networks. These processes are continuing to develop at 25 days post plating (Fig. 1B). This *in vitro* evidence suggests that MMs may aggregate in sinusoids or elsewhere with the effect of forming a similar network of processes potentially to trap foreign particles or organisms moving through the vessel. Johnson et al. (1999) demonstrated that MMs in culture phagocytized red blood cells and bacteria, and that they attached to parasites.

The Use of PIT Tags in Capture-Recapture Studies of Frogs: A Field Evaluation

GRAHAM H. PYKE
Frog Ecology and Behavior Group, The Australian Museum
6 College Street, Sydney, N.S.W., 2010, Australia
e-mail: grahamp@austmus.gov.au

Marking animals so that they can be individually identified is an essential component of many animal studies. However, the same animals must be observed on two or more occasions for patterns of growth, development, movement and other parameters to be determined (e.g., Donnelly et al. 1994; Schemintz 1980; Skalski and Robson 1992). Capture-recapture of individuals may also be required for estimation of population size and patterns of population dynamics (e.g., Begon 1979; Caughley 1984; Seber 1982; Southwood 1978).

To be useful in these contexts the marks applied to animals should be able to uniquely identify the individual, should be permanent (at least over an animal's lifetime) and accurately discernable, and should not affect survival, reproduction or behavior (e.g., Seber 1982). Additionally, if marked animals are less likely to be captured than unmarked animals then estimates of population size based on capture-recapture analysis will be biased away from the true population size (e.g., Seber 1982). Any process of marking animals must also be logistically and economically viable (e.g., IUCN/CBSG on Permanent Animal Identification 1991).

For the use of marks to be justified, any associated pain or suffering experienced by the animals should be minimized (e.g., Anonymous 1992). Aside from being reasonably humane, such an approach is now a legal requirement in many areas for research activities that involve non-human animals.

In the case of frogs, no reliable and completely pain-free technique for marking individuals has been found. Identifying individuals on the basis of unique color patterns is sometimes possible, but only when the total number of individuals is reasonably small (e.g., Berrill et al. 1992; Bertram and Berrill 1997; Doody 1995). It is difficult or impossible to permanently attach anything external to the body of a frog (e.g., Elmberg 1989; Woodbury 1956), and therefore the most commonly used technique for marking frogs has been toe-clipping (e.g., Donnelly et al. 1994). In this technique, one or more toes are removed and a unique pattern of toe removal is assigned to each individual (e.g., Donnelly et al. 1994). It is hard to imagine that this would not be painful for the animals involved. Branding, where a mark is induced in the skin of a frog through the application of intense but localized heat or cold (e.g., Clark 1971; Ehmann 2000), seems also likely to be painful for the individuals involved.

Since 1983 it has been possible to mark individual animals with small passive integrated transponders that are generally referred to as PIT tags or microchips (e.g., Barnard 1989; Camper and Dixon 1988; Fagerstone and Johns 1987; Prentice and Park 1983). The transponder is an integrated unit consisting of an electromagnetic coil, tuning capacitor and microchip, all sealed in a cylindrical glass enclosure that is typically 1.8–2.2 mm in diameter and 10–

12 mm long (e.g., Elbin and Burger 1994; Fasola et al. 1993; Keck 1994; Ott and Scott 1999). The transponder is passive in that it contains no power supply and does not emit any signal until stimulated (e.g., Germano and Williams 1993; Jehle and Hoedl 1998; Schooley et al. 1993). The chip is inserted internally into the animal and is programmed with a unique alphanumeric code that can be read by a scanner (e.g., Christy 1996; Jehle and Hoedl 1998; Schooley et al. 1993).

This methodology has many advantages of alternative methods for marking animals. As there are high rates of scanner accuracy (Gibbons and Andrews 2004), PIT-tagged individuals can consistently be identified with little or no error. PIT tags are reliable and relatively easy to use, durable and afford an immense number of possible different codes, estimated at about 34 billion (Elbin and Burger 1994). Insertion of a tag into an animal requires no more than five minutes (Christy 1996) and often much less time (G. Pyke, pers. obs.). Tag life is considered to be 15–20 years (Germano and Williams 1993), 50–100 years (Pope and Matthews 2001), indefinite (Christy 1996; Fasola et al. 1993; Keck 1994) or 'permanent' over the lifetime of an animal (Ott and Scott 1999).

Due to these advantages and the small size of PIT tags, they have been increasingly used to individually mark all classes of vertebrate animals (Elbin 1991). They have been used with fish (e.g., Adam and Schwevers 1994; McCutcheon et al. 1994; Peterson et al. 1994), mammals (e.g., Ball et al. 1991; Schooley et al. 1993; Thomas et al. 1987), reptiles (e.g., Germano and Williams 1993; Parmenter 1993; Jemison et al. 1995), amphibians (e.g., Brown 1997; Donnelly et al. 1994; Zulich et al. 1992), and birds (e.g., Ballard et al. 2001; Elbin and Burger 1994). They have also been used with relatively large invertebrates, such as crabs (e.g., Pengilly and Watson 1994).

The consequences of the PIT tagging process for the animals involved have been considered in a number of studies. For example, relative merits of using PIT tags in relation to alternative methods for individually marking animals have been assessed (e.g., Brown 1997; Jehle and Hoedl 1998; Jemison et al. 1995; Ott and Scott 1999; Perret and Joly 2002), as have effects of PIT tagging on individual survival, growth, movement and health (e.g., Christy 1996; Fasola et al. 1993; Keck 1994; Ombredane et al. 1998). In general, PIT tagging has minimal adverse impacts on tagged animals (Gibbons and Andrews 2004).

Our own use of PIT tags to mark frogs provides an additional opportunity to consider some of the consequences of employing this technique. As part of an ongoing research program that focuses on the Green and Golden Bell Frog (*Litoria aurea*) and the Striped Marsh Frog (*Limnodynastes peronii*) my colleagues and I have been using PIT tags to mark frogs at several sites in New South Wales, Australia since March 1998 (Pyke and Miehs 2003; Pyke and White, unpubl.). We have PIT tagged over 3000 individual frogs and had multiple recaptures of many of these. We have, therefore, made a number of observations that are relevant in the context of evaluating the outcomes of the technique.

Field Studies

General Methodology.—Field studies have been carried out by teams of people that have varied in composition. These teams have been coordinated by the author, who has been present on all occasions.

We have used PIT tags supplied by Trovan in individually-packaged needles inside hermetically sealed packages. Inside each needle is a metal rod that can push the tag from the open end of the needle. We have implanted these tags subcutaneously by pinching the skin along the side of the body a short distance behind the front limb, inserting the needle through the pinched skin parallel to the body axis toward the base of the hind limb, and then pushing the tag through and out of the needle with the aid of a plunger mechanism inside a syringe that is attached to the needle. We have not anaesthetized frogs before this procedure. To seal the wound area we have used Vetbond, an n-butyl cyanoacrylate adhesive that quickly polymerizes from liquid to solid state when applied to the skin. We have adopted a minimum snout-vent length of 40 mm for PIT tagging. The alphanumeric codes for the PIT tags supplied to us have not been sequential and have varied greatly from one to the next.

We have been able to evaluate PIT tags of two different ages since manufacture. We have used PIT tags within two years of their receipt and well before the stated expiry date, which has been about seven years after we received them. These tags would have been less than two years old when used by us. We also have some PIT tags with an expiry date of 1996, but have not used them. These tags were considerably older when we examined them, probably about 15 years since manufacture (see below).

Effects of PIT Tagging on Frogs.—During field studies in Australia over a period of 6 years we have implanted PIT tags under the skin of almost 3000 frogs of nine species. One species, the Green and Golden Bell Frog (*Litoria aurea*) has accounted for most (89.2%, N = 2950) of the frogs we have micro-chipped, followed by the Striped Marsh Frog (*Limnodynastes peronii*; 8.9%) and small numbers of the other species.

The behavior of frogs while we have microchipped them suggests that any pain involved must be minimal, except when an animal is injured during the process. Although capable of emitting a distress call, the frogs that we have PIT tagged have rarely (i.e., <1% of the time) made such calls while we have handled and tagged them (pers. obs.). They have also rarely flinched or otherwise struggled during the microchipping. On the other hand, on three occasions when frogs have clearly been injured during tagging (see below) they have made loud and obvious distress calls. I assume here that distress calls and struggling movements of hand-held animals are possible signs of pain they experience, and that the absence of such behaviors suggests a lack of pain.

On only three occasions has any noticeable injury occurred to a frog during the tagging process. In each of these cases the implanting needle must have penetrated the body wall, because part of the lungs exuded from the body and out into the air almost as soon as the needle was withdrawn, and the frog emitted loud distress calls starting when the needle began to penetrate the body wall. In one case the injured frog was taken from the wild into captivity, given sutures, antibiotics and food, and subsequently released back into the wild. In another case, the lungs naturally and reasonably quickly retracted back into the frog's body and remained there after application of tissue glue to the wound, and this frog was then released where it had been captured. In the third case the frog was euthanized. Neither of the injured frogs that were released alive has subsequently been recaptured, but overall recapture rates at the associated sites have been close to zero (Pyke,

unpubl.).

No longer-term effects of our tagging on the health of individual frogs have been apparent. Whenever frogs have been recaptured about 24 h after initial tag insertion, a thin layer of Vetbond around the wound site has often been observed but the wound itself has never been visible and there have been no signs of swelling, infection or other damage to the area (N = 420). Frogs that have been recaptured about 6 weeks or longer after initial tag insertion have never shown any signs of the wound or other damage to the area (N = 1099). Our field schedule has been such that recaptures after intervals of between 2 days and 6 weeks have not been possible.

The proportion of tagged frogs among those found dead has not been significantly different from the proportion among those captured alive, suggesting that mortality is no different between tagged and untagged frogs. At Broughton Island over the period from 1999 to 2003 four dead frogs (3 *L. aurea*; 1 *L. peronii*) have been found, of which three (i.e., 75%) were tagged. Over this period, which omits the first year of the study when recapture rates were rapidly increasing, and during which recapture rates were relatively stable, the overall recapture rate across the two species was almost identical at 74.5% (N = 5379). Similarly, at North Avoca over the same period, 33.3% (N = 9) of *L. aurea* frogs found dead had been tagged compared with 48.1% (N = 497) of this species captured alive (P = 0.5; Fisher Exact Test).

If tagged frogs are less likely to mate than untagged frogs then the proportion of tagged frogs among those found in amplexus should be lower than the proportion among unmated frogs, and a significant trend in this direction was found. On Broughton Island, during spring and summer when almost all amplexing *L. aurea* are found, 60.9% of the males (N = 46) and 37.0% of the females (N = 46) were tagged while among unmated frogs, 80.0% of males and 62.4% of females were tagged (males: P = 0.003; females: P = 0.001; Fisher Exact Test). Amplexing pairs of this species have not been recorded at other sites.

However, the frogs in amplexus were significantly younger than those that were unmated. For those *L. aurea* that had been previously captured and tagged, the average number of captures per individual was significantly higher for unmated frogs than for frogs in amplexus (i.e., unmated: mean = 5.45, N = 4229; amplexing frogs: mean = 3.76, N = 54; F-ratio = 9.11 r^2 = 0.002, P = 0.003, ANOVA). For all captured *L. aurea*, including both new captures and recaptures, the average number of captures per individual was about 92% higher for unmated frogs than for frogs in amplexus (i.e., unmated: mean = 4.32, N = 5661; amplexing frogs: mean = 2.24, N = 120; F-ratio = 31.7, r^2 = 0.005, P<0.001, ANOVA). Assuming the probability of capture for a frog of this species is independent of age once the frogs have reached maturity, the average age of the unmated frogs must have been about 92% higher than that of the amplexing frogs.

Taking this age difference into account, there were no significant differences in recapture rates of amplexing and unmated frogs. If the probability of an individual of age "X" being tagged is "P_X" and the probability of an animal being captured is assumed constant throughout its life, then the probability of an individual of age "A times X" being tagged, where A is any constant, is $1-(1-P_X)^A$. Hence the recapture rates of 0.609 and 0.370 for amplexing males and females respectively are equivalent to 0.835 and 0.588 among frogs that are 92% older (e.g., $1-(1-0.609)^{1.92}=0.835$). These proportions are not significantly different from those observed for unmated males and females (P's = 0.8 and 0.5, respectively; Fisher Exact Test). Allowing for the likelihood that capture probability does not remain constant would not alter this conclusion.

During our study some PIT-tagged frogs of *L. aurea* have lived for many years, some individuals have been captured many times, and recapture rates have reached high levels. Based on recaptures, about 7% of tagged individuals have lived at least 3 years since first capture and several frogs have been alive for the 5-year duration of the study. About 8% have been captured at least 10 times and about 1% have been captured over 20 times. Recapture rates have peaked during winter each year at about 90% for males and 75% for females (Pyke, unpubl.).

Permanence of Tag Code and Accuracy of Recording Codes.—No tag failures have been detected during the present study. For most tagged individuals the tag can be seen as an elongated bump under the skin and there has not yet been a case where a tag was visible but undetected by the scanner. In a relatively small number of cases the scanner has detected a tag that was not noticed during visual inspection of the frog. Tag failures have, however, been apparent in tags that were about 15 years old. Out of a total of 75 tags that all have an expiration date of 1996 printed on the sealed container and were supplied together, 5 (i.e., 7%) could not be read by a scanner in 2004, while the remainder could be read correctly.

There has probably been negligible error with regard to the alphanumeric codes associated with the PIT tags when they have been implanted into frogs. In our case the PIT tags come supplied with stick-on labels bearing the code and we have used these labels to record the code without scanning and hence without any scanning error. We occasionally scanned the PIT tags at the time of implantation and always found agreement between the code detected by the scanner and the code on the label. We have also been able to compare the codes associated with the tags we have used with a master list for tags supplied to us, and so far found no discrepancy.

On the other hand, we have detected incorrect codes in our data when codes that are recorded for a recaptured frog only appear once in our records and have never been recorded in association with an initial capture of any animal. About 1.8% of recorded codes for frogs on Broughton Island have shown such errors (N = 5020). Such errors might also be detected if recorded microchip codes do not correspond to the entries in the master list of all codes that have been used.

We have found that these errors can generally be attributed to human error associated with recording microchip codes, with usually just one character being omitted or incorrectly recorded. Most cases of mistaken character identity can be attributed to visual or auditory similarity between the correct and incorrect characters when written or spoken respectively (e.g., visual: B vs. 8; auditory; D vs. B). Some mistakes have no obvious explanation.

We have taken steps to minimize recording errors. Typically one person scans and calls out the code to a second person that does the recording. Lighting may be poor and there may be significant background noise. To minimize recording error the person doing the scanning uses a headlamp to illuminate the scanner. To minimize auditory misinterpretation, words rather than letters are called out (e.g., 'alpha' instead of 'a'). Errors could be further

reduced if the recording person called out the recorded code to the scanning person who checked this against the code on the scanner, but this would add to the time required.

Through the diversity, as supplied, of alphanumeric codes for PIT tags and the above steps to minimize human error, we have been able to achieve a marking system that is essentially error-free. There is much noticeable variation among the alphanumeric codes for PIT tags, both within batches of supplied tags (we get them in batches of 40) and between these batches. It is this diversity of codes that permits us to detect and correct any errors that do occur, despite our attempts to minimize them. Such errors might also be eliminated where it is possible to transmit detected codes directly from scanner to computer and match these codes with other recorded information about individual frogs.

Discussion

Our field observations provide further evidence that marking frogs with PIT tags has little immediate impact, does not significantly affect long-term survival or reproductive behavior, and can be used with almost no error (see Gibbons and Andrews 2004). The behavior of frogs while we have microchipped them suggests that any pain involved must be minimal, they have rarely suffered noticeable injury during the tagging process, and no longer-term effects of our tagging on the health of individual frogs have been apparent. There have been no apparent differences between tagged and untagged frogs in terms of survival or ability to mate. Some tagged frogs have lived for many years, some individuals have been captured many times, and recapture rates have reached high levels. The diversity of alphanumeric codes for PIT tags and our steps to minimize human error have essentially eliminated errors. Hence there are many benefits associated with the use of PIT tags to mark amphibians and other animals.

Our observations, however, are more consistent with claims that tag life is 15–20 years (Germano and Williams 1993) than with reported tag longevities of 50–100 years or indefinite (Christy 1996; Fasola et al. 1993; Keck 1994; Pope and Matthews 2001). Assuming that our older tags were initially obtained in about 1989, then 7% have stopped working after about 15 years. Of course, it is also possible that longevity has increased through improved technology. Authors (e.g., Keck 1994) seldom comment regarding tag failure and so presumably this has rarely occurred. However, there has not yet been a comprehensive evaluation of tag longevity.

Acting as impediments to more widespread use of PIT tags for marking frogs are their size and cost. With a minimum snout–vent length threshold of 40 mm, given the smallest size tags currently available, there are many frogs that cannot be marked in this manner. As financial resources will always be limiting, the high cost of PIT tags relative to other methods of marking frogs also restricts their use (e.g., Elbin and Burger 1994; Germano and Williams 1993; Gibbons and Andrews 2004; Ireland et al. 2003; Ott and Scott 1999). However, given the considerable benefits associated with their use for marking animals, they are likely to be increasingly used in this manner, especially with decreases in either their size or cost.

Acknowledgments.—This research has been supported by the Australian Museum, a NSW Government Enhancement Grant and personal resources. It would not have been possible without large amounts of time contributed by numerous volunteers and without accommodation and other facilities provided by the Esmerelda Fishing Club and other owners of the cabins on Broughton Island. It would have also been impossible without the assistance of Greg Gowing, who developed and maintained a computerized database for the project, participated in field work, discussed aspects of the project, and provided comments and suggestions with regard to an earlier version of this paper. This research complied with all applicable institutional Animal Care guidelines and was carried out under Australian Museum Animal Care and Ethics Approval 96/02. A Scientific License (A2410) was issued by the New South Wales National Parks and Wildlife Service.

Radio telemetry is a useful technique in ecological studies to determine habitat use, survival, and dispersal of organisms (Faccio 2003; Lamoureux et al. 2002; Millspaugh and Marzluff 2001). For amphibians, radio transmitters are attached externally using a belt harness or implanted into the coelomic cavity (Muths 2003; Werner 1991). External attachment of transmitters may affect amphibian dispersal or other life cycle events (e.g., breeding, feeding; Richards et al. 1994). Also, external transmitters are not feasible for amphibians that estivate underground, because they could interfere with digging and concealment. Alternatively, implanting transmitters requires invasive surgery that might affect body condition and survival (Madison and Farrand 1998), or damage vital organs within the coelomic cavity. Also, information on aboveground signal range of transmitters after implantation has not been published. Our goal was to describe the general effects of implant transmitters on coelomic response of a common amphibian (*Bufo cognatus*) in the Great Plains (Gray et al. 2004), and measure aboveground signal distance over four months, which was the expected battery life of the transmitters.

Materials and Methods.—We collected 14 Great Plains Toads

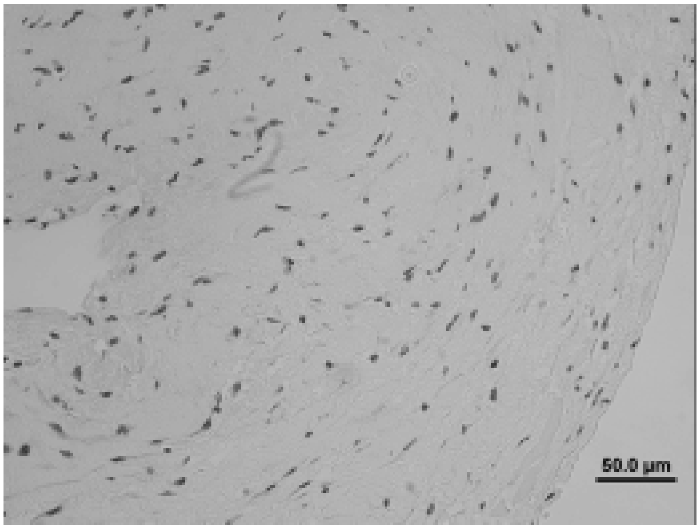

FIG. 1. Four months post-surgery microscopic view of the connective tissue encapsulating transmitters implanted in the coelomic cavity of 9 *Bufo cognatus*.

(*Bufo cognatus*) along roads at night during intense rain on 12 May 2001 northwest of Lubbock, Texas (33˚39'–33˚51'N, 101˚49'–102˚10'W) in the Southern High Plains. We placed all toads in separate 38-liter aquariums and fed them native crickets and beetles *ad libitum* for the duration of the study. Each aquarium contained 10 cm of soil substrate and a 500 cm^3 plastic water reservoir that was flush with the substrate surface to allow natural burrowing and water absorption by the toads.

We used SM1-H transmitters manufactured by AVM Instrument Company. These transmitters were single-staged (150 MHz) and powered by a CR2040 lithium manganese dioxide cell with an internal-loop antenna that encircled the battery. Signal strength and pulse rate of our transmitters at the beginning of the study were between -21 and -25 dBm and 58 and 68 BPM, respectively. The expected battery life given the power output (0.065 mA) was 4 months. The transmitter, battery, and antenna were encapsulated in RTV plastic and coated with clear dental acrylic. The final mass and volume of the transmitter package were 6.63 g (5–10% of individual toad body mass, 60–118 g) and 2.45 cm^3, respectively.

We implanted transmitters into 10 of the 14 toads on 2 June 2001. The four remaining toads did not receive transmitters and were maintained in captivity simultaneously. These toads were used as controls so we could compare histological responses to the transmitters at the end of the study. Our surgical procedures were similar to Madison (1997) and Seebacher and Alford (1999). We soaked transmitters and surgical instruments ≥ 30 minutes in chlorhexadine then rinsed them with sterile water. Toads were anesthetized by placing them into a solution of distilled water and tricaine methanesulfonate (1000 mg/L, Faccio 2003); sedation occurred within 10–32 minutes (mean = 18.5, SD = 6.8). After anesthetization, we made a 20-mm skin incision in the left caudoventrolateral quadrant of the abdomen with a sterile #20 scalpel. Next, we punctured through the abdominal wall and into the coelomic cavity with closed pointed surgical scissors. After puncturing the wall, the scissors were opened to separate the muscular fibers creating an opening into the coelomic cavity. The opening was maintained with thumb forceps then the transmitter was placed into the cavity. The incision was closed in two layers with 3-0 absorbable suture material. First, we sutured the abdominal wall with 3 stitches 5 mm apart in a simple interrupted pattern. Next, we closed the skin in a similar fashion. The incision was dried using sterile 4 × 4 gauze sponges. Finally, we applied surgical glue along the entire length of the incision to provide a temporary sealant. The entire surgical procedure lasted 8–10 minutes. Toads were then placed in distilled water containing antibacterial tetracaine powder (1% solution) for recovery (mean = 40.6, SD = 11.7 minutes). After anesthetic recovery, we returned toads to aquariums.

We measured aboveground signal distance (m) and body mass (g – transmitter package mass) twice per month from 2 June to 2 October 2001. We used a fully charged R2100 Advanced Telemetry Systems receiver and a 3-element AF Antronics Yagi antenna (model #F152-3FB) tuned specifically for 150–152 MHz to measure signal distance. Aboveground distance was determined by placing each toad in a plastic bucket and traversing a linear transect until the signal was not received. We considered these measure-

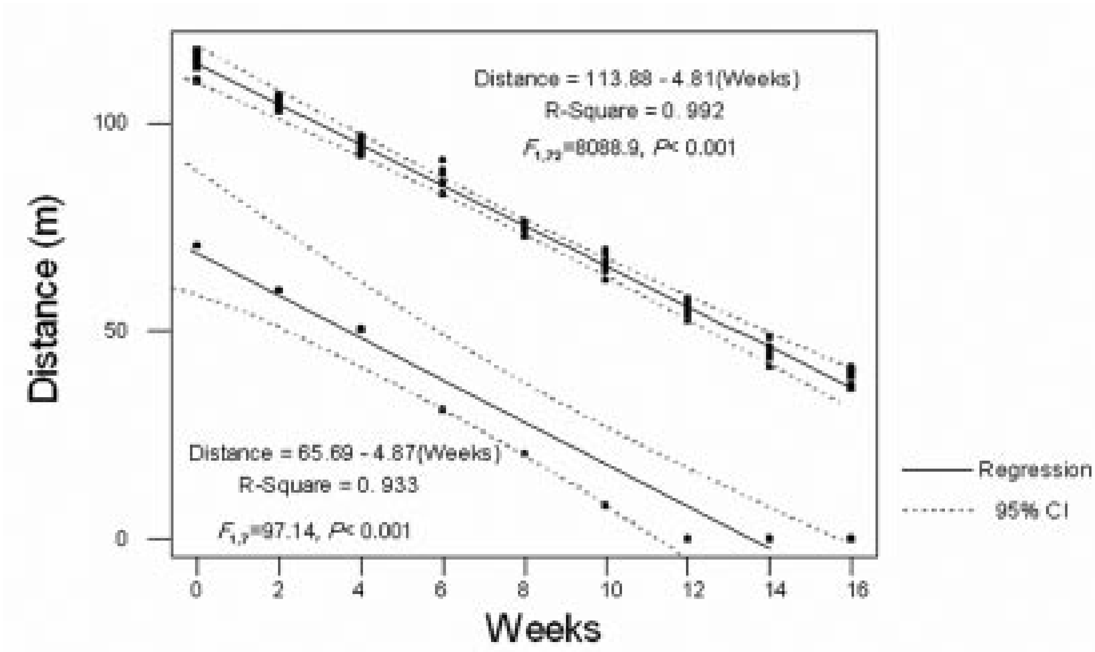

FIG. 2. Aboveground signal distance in two-week increments (2 June [week = 0] – 2 October 2001 [week = 16]) of SM1-H internal-loop antenna transmitters implanted into 10 Great Plains Toads (*Bufo cognatus*). The bottom regression is for a prototype transmitter that lost battery strength prior to the study.

ments maximum signal distances under ideal conditions because toads were aboveground and no obstructions existed between them and the receiver. Individual toad survival also was recorded.

At completion of the study, we sent all live toads (controls and ones with transmitters) to the University of Georgia Tifton Veterinary Diagnostic and Investigational Laboratory where they were euthanized and necropsied. Macroscopic inspections included surgical site condition, coelomic response to transmitters, and general organ condition. Tissue sections of all organs (including skin) were collected, processed, and examined microscopically.

Aboveground signal distance and toad body mass were regressed against post-surgery duration in two-week increments from the initiation until the end of the study (0, 2, 4, …, 16 weeks) to compare signal range and body mass through time. We performed two separate regressions for signal distance because maximum distance of one transmitter was markedly less throughout the study compared to the other nine transmitters. This transmitter was sent as a prototype six months prior to the study and used twice; all other transmitters had batteries at full strength at the beginning of the study. Also, one toad died during the study on 5 July 2001 thus its signal distance was not measured afterward nor used in the regression after week 4. Proportion of toads surviving until the end of the study was tested against a constant proportion ($p_0 = 0.5$) using a one-sample binomial test to determine if the overall survival rate differed ($\alpha = 0.05$) from the mortality rate (Milton and Arnold 1995:322). Necropsy results are presented as summary statistics.

Results.—Pathological examinations were performed on 9 of the 10 toads with transmitters and the 4 control toads. The deceased toad could not be analyzed because of advanced autolysis. Surgical sites of all toads were healed with minimal scarring. Granulation tissue existed at the surgical site of all toads and few mixed inflammatory cells (heterophils, macrophages, and lymphocytes) were present in one toad (11.1%). All transmitters were in the right caudoventrolateral coelome except one, which was in the left caudoventrolateral coelome. Each transmitter was encapsulated in a smooth, transparent connective tissue <1 mm thick (Fig. 1); few inflammatory cells and occasional vascularization were noted in the capsule of one transmitter. Six of 9 transmitters (67%) were adhered to the coelomic wall only or to the coelomic wall and 1–2 nearby organs by a strand of fibrous tissue (hereafter adhesion) that was ≤ 1 mm diameter × 1–4 mm in length. Organs of attachment included the liver, ovary, and mesentery. Histological analyses and comparison with control toads revealed no damage to the organs of attachment or other organs (i.e., lungs, spleen, kidneys, large and small intestines) in the coelomic cavity.

Aboveground signal distance decreased predictably through the study (Fig. 2). Mean aboveground signal distance at the initiation and completion of the study for the 9 transmitters was 114.2 m (SD = 2.7) and 39.4 m (SD = 1.9), respectively. The maximum distance of the prototype transmitter at the initiation of the study was 70.4 m with no signal by week 12. Toad body mass did not change ($F_{1,7} = 0.03$–5.10, $P = 0.06$–0.86) throughout the study. The proportion of toads surviving was 0.90, which differed ($P = 0.011$) from $p_0 = 0.5$. Mortality of the one toad was due to post-surgery complications; one suture pulled through the skin causing secondary infection.

Discussion.—Our results suggest that intracoelomic placement of radio transmitters does not negatively affect survival, body mass, and coelomic condition of amphibians. Post-surgery survival was 90% and body mass of all individuals was stable for the duration of the study. Previous studies also have suggested that survival and body mass are unaffected by implant transmitters (Madison 1997; Madison and Farrand 1998; Werner 1991).

Intracoelomic placement of transmitters was within the left caudoventrolateral quadrant, but at postmortem examination, 8 of 9 transmitters were found in the right caudoventrolateral quadrant. Although the exact mechanism for transmitter displacement is unknown, it may have been a consequence of stomach expansion. The stomach is located within the left middle coelome (Duellman and Trueb 1994). During feeding and subsequent stomach expansion, the stomach may have extended into the left caudal region, displacing the transmitter to the right. Once displaced, the transmitter may not have returned to the left caudal position after gastric emptying.

Coelomic response to the transmitters was similar for all toads. A thin transparent connective tissue capsule formed around all transmitters, which is a typical histological response to implants (Butler et al. 1997; Eltze et al. 2003; Kellar et al. 2002; Laitung et al. 1987; Shannon et al. 1997; Walboomers et al. 1998; Walboomers and Jansen 2000; Zhao et al. 2000). One capsule had minimal vascularization and inflammatory cell infiltrates, which was consistent with local irritation. Most toads developed one or more fibrous adhesions that resulted in anchoring the transmitters within the coelome. Adhesions are common surgical complications in all species, and they result from local trauma as well as constant irritation (Alimoglu et al. 2003; Goodwin and Grizzle 1991; Herzog et al. 1970; Montz et al. 1991). In general, adhesions are not considered beneficial structures; however in our toads, the adhesions may have aided in preventing mechanical trauma to nearby organs or preventing cranial migration during normal body movements by anchoring the transmitters locally.

Coelomic and body mass response to implants likely would be similar for other large anurans (e.g., > 60 g in body mass). Mortality of one toad occurred secondary to dehiscence of the surgical site, which has been documented previously (Werner 1991). Thus, we recommend external sutures encompass > 2 mm of skin on each side of the incision. This may be especially important for species that are fossorial such as *Bufo cognatus*.

Average aboveground signal distance at the beginning of the study was 114 m and decreased linearly over the 4 months to 40 m. This initial signal distance was 23% of the manufacturer's claim of 500 m. Only 1 of 10 transmitters lost signal in < 4 months (the expected battery life); this transmitter was the prototype and may have been operating at a reduced power capacity at the initiation of the study.

Considering that average aboveground signal distance of our implant transmitters was approximately 100 m, researchers may need to monitor amphibians frequently (1–2 times/day) in the field so they are not lost. Also, implant transmitters might not be reasonable for amphibian species that disperse long distances over short duration. New multi-staged transmitters (e.g., G3-1V) may have greater signal range than the SM1-H transmitters used in our study (B. Corbett-Kermeen, AVM Instrument Company, pers. comm.). Signal distance also might be reduced by environmental variables that we did not measure, such as aboveground vegeta-

tion and substrate (if amphibians become fossorial, Madison 1997). Thus, our distance estimates likely represent best-case scenarios of signal range for SM1-H implant transmitters.

Observations on Problems with Using Funnel Traps to Sample Semi-Aquatic Snakes

JEFFREY D. CAMPER
Department of Biology, Francis Marion University
Florence, South Carolina 29506, USA
e-mail: jcamper@fmarion.edu

Funnel traps have been shown to be an effective method for sampling snakes in many different aquatic habitats (Fitch 1999; Greene et al. 1999; Karns et al. 2000; Keck 1994). However, any technique can have biases which need to be considered when choosing an appropriate sampling method. In this note I report problems encountered using funnel traps to sample snakes. These problems include: 1) predation upon trapped Banded Watersnakes (*Nerodia fasciata fasciata*) by Eastern Cottonmouths (*Agkistrodon piscivorus piscivorus*); 2) potentially biased sex ratios of *N. fasciata* and *A. piscivorus*; and 3) predation upon trapped snakes by red imported fire ants (*Solenopsis invicta*).

I used both commercially available minnow traps of dimensions 42 cm long by 22 cm in diameter (Cuba Specialty Manufacturing Co., Filmore, New York; funnel openings enlarged to 3 cm with a rake handle), and funnel traps made from hardware cloth that were 41 x 22 cm with 5-cm funnel openings (Fitch 1987) to sample *N. fasciata* and *A. piscivorus.* The study site was the Pee Dee Research and Education Center (PDREC), a 972-ha experimental farm owned by Clemson University, located in the upper coastal plain of Darlington County, South Carolina, USA. Traps were

placed in shallow water (water depth < trap diameter) along logs, in emergent vegetation, and along short drift fences. The drift fences consisted of 5-m lengths of aluminum flashing oriented perpendicular to the shoreline with two traps placed at each end. Because of low capture rates (0.007 captures/trap day [TD] in 1998 to 0.011 captures/TD in 2002), traps were checked at 48-h intervals and not on weekends. Beginning in 1998 I sampled 11 ponds, a swamp, a lake, and several drainage ditches. Sampling occurred from July–October 1998 (960 TD), May–October 1999 (4108 TD), May–July 2000 (994 TD), April–June 2001 and 2002 (810, 994 TD, respectively), and May–June 2003 (757 TD). Means are followed by ± 1 SD. An $\alpha \leq 0.05$ is considered significant in all statistical tests.

Ten female *N. fasciata* ranging from 362 to 738 mm snout–vent length (SVL, mean = 600.8 ± 102.7) were found dead in traps with live Cottonmouths, including three (19% of captures) in 1998, two (7% of captures) in both 1999 and 2000, two (18% of captures) in 2002, and one (12.5% of captures) in 2003. The largest dead specimen was found in a minnow trap with a live male conspecific (390 mm SVL) and a live *A. piscivorus*. Of six adult *A. piscivorus* trapped with dead watersnakes, four were male and all ranged from 521 to 810 mm SVL (mean = 706 ± 115.7). Necropsies of 10 dead *N. fasciata* revealed paired puncture wounds surrounded by necrotic tissue on the dorsum of eight. I was unable to find bite marks on two specimens that were in an advanced state of decomposition. Bite marks (paired puncture wounds) were located 85–502 mm (mean = 223.75 ± 156.59) posterior to the snout. One 680 mm SVL specimen was bitten twice (two pairs of puncture wounds) located 502 and 585 mm posterior to the snout. *Nerodia fasciata* has been reported in the diet of Cottonmouths (Palmer and Braswell 1995), but only two of the watersnakes (362, 595 mm SVL) appeared to have been ingested and regurgitated as evidenced by saliva on the body of the dead *Nerodia*. Upon checking the trap, the larger of these was being ingested headfirst with only the posterior 10 cm protruding from the mouth of the *A. piscivorus* (617 mm SVL male) but was regurgitated when the trap was picked up. It is unclear why not more of the *N. fasciata* were ingested, although it is possible that cottonmouths either regurgitated the *Nerodia* after becoming agitated in the traps or did not have enough space to maneuver the *Nerodia* into proper swallowing position. However, it is also possible that the *Nerodia* were bitten as a stress response.

Sex ratios are an important part of population structure. Females dominated the samples of Banded Watersnakes and Eastern Cottonmouths. The 67 *N. fasciata* sampled from this population exhibited a 1.68:1 female-biased sex ratio, which was significantly different from 1:1 ($\chi^2 = 4.83$, df = 1, P = 0.028). The primary sex ratio of 66 neonate *N. fasciata* from three litters in this population was 1.2:1, which was not significantly different from 1:1 ($\chi^2 = 4.684$, df = 2, P = 0.096; unpubl. data). I believe this female bias to be a sampling artifact because of the primary sex ratio and because observations based upon radiotelemetry suggest that male *N. fasciata* in this population frequent deeper water more often than females (pers. obs., 2002) and therefore might be less likely to encounter funnel traps restricted to the littoral zone of aquatic habitats. Secondary sex ratios for a Texas population of *N. fasciata* sampled with funnel traps also showed a female bias (Keck 1994). I found a similar trend in 63 *A. piscivorus* from the Pee Dee population, as my sample yielded a 1.52:1 sex ratio that was not significantly different from 1:1 ($\chi^2 = 3.11$, df = 1, P = 0.078). Three other populations of *A. piscivorus* had balanced or male-biased sex ratios (Blem 1981; Ford 2002; Zaidan 2001).

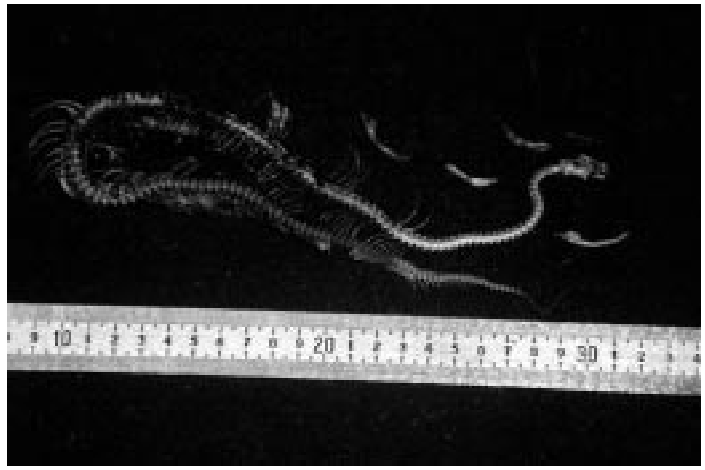

FIG. 1. Remains of a female Eastern Cottonmouth (*Agkistrodon piscivorus piscivorus*) attacked by red imported fire ants (*Solenopsis invicta*) while caught in a funnel trap at the Pee Dee Research and Education Center in Darlington, Co. South Carolina found on 9 June 1999.

Red imported fire ants (*Solenopsis invicta*) are problematic for many species of North American wildlife (Mount 1981). On 9 June 1999, a female *A. piscivorus* ca. 495 mm in length (skull and remaining vertebral column length) was found in a trap that was swarming with fire ants. The snake was reduced to a skeleton with only a small amount of viscera and the medial portions of some of the ventral scales remaining (Fig. 1). As no other cause of death was evident, it is likely that the snake was killed and devoured by fire ants. The trap had been placed perpendicular to the bank over a hole in very shallow water on 7 June 1999. If the trap had been placed in deeper water the ants probably would not have been able to attack the snake. Although fire ant predation on reptile eggs and hatchlings has been well documented for crocodilians, lizards, and turtles (Allen et al. 1994; Epperson and Heise 2003; Landers et al. 1980; Martin 1989; Moloney and Vanderwoude 2002; Mount 1981), I could find no evidence of fire ant predation on snakes in the literature. However, Tuberville et al. (2000) implicated fire ant predation in the decline of the Southern Hog-nosed Snake (*Heterodon simus*).

In conclusion, funnel traps can be an effective way to sample semi-aquatic snakes but frequent monitoring of traps, trap placement away from fire ant mounds, and possible bias in sex ratios should be considered when employing this technique.

Acknowledgments.—This work was supported by Francis Marion University Faculty Professional Development Funds, South Carolina Department of Natural Resources (SCDNR) and by the Summer Paid Research Intern program of the South Carolina Governor's School for Science and Mathematics. Evaluation of a New Method for Measuring Salamanders

LEE J. WALSTON[1]
and
STEPHEN J. MULLIN
Department of Biological Sciences, Eastern Illinois University Charleston, Illinois 61920, USA

[1]*Corresponding author; e-mail: ljcwalston@yahoo.com*

Collection of morphometric data is essential to many field studies of amphibian populations. One of the most common measurements obtained from salamanders is snout-to-vent length (SVL), a parameter useful in studies of sexual dimorphism (Bovero et al. 2003), demography (Semlitsch 1985), and systematics (Carlin 1997). Measuring salamander lengths in the field is challenging because of their small size, slimy texture, and propensity to maintain a nonlinear body position. Time expenditure is another concern, especially when researchers process large numbers of salamanders. Different measurement techniques vary in accuracy and precision, limiting the reliability of the data so that comparisons cannot be easily performed. Here, we compare a new method of obtaining salamander SVL measurements to other commonly used methods.

To restrict salamander movement and maintain a linear body orientation, we constructed a device (the "Salamander Stick") using two equally sized polyvinyl chloride (PVC) pipes (40-cm long, with 2.5 cm outer diameter). We wrapped duct tape around both ends of one PVC piece such that a gap of 2 mm separated the two pieces when positioned parallel to each other. We then wrapped duct tape around both ends of the device, which secured the 2 mm gap. After assembly, we could pass a 23-cm wide plastic sandwich bag through the gap while prohibiting the passage of objects larger than 2 mm thick (Fig. 1a).

To obtain salamander SVL measurements, we placed a salamander into a plastic sandwich bag and fed the bag opening through the gap between the two PVC pipes. We pulled the bag through the gap until the salamander (at the bottom of the bag) reached the gap. We then manipulated the salamander through the walls of the bag to straighten it along the cranio-caudal axis and ensure that its ventral surface could be viewed. Once this was accomplished, SVL measurements were obtained with dial calipers (Fig. 1b).

We compared the precision and accuracy of the Salamander Stick to two other methods. In Method 1 (hereafter, "Freehand"; adopted from Phillips et al. 2002), a salamander was set on a table, straightened, and the SVL was measured with a plastic ruler. In Method 2 (hereafter, "Tube"; adopted from Mathis 1991), a salamander was placed into a clear plastic tube (inner diameter = 1.7 cm) and the SVL was measured by placing a ruler against the outside of the tube.

In March 2004, we captured 20 adult smallmouth salamanders (*Ambystoma texanum*) from a breeding pond in Coles County, Illinois, USA. During measurements, we housed all salamanders individually in 2 L plastic tubs in the laboratory. Salamanders were randomly selected and measured (SVL ± 1.0 mm) once with a

randomly chosen method. We repeated this process until each salamander was measured 4 times for each method. A plastic ruler was used to measure salamanders from the tip of the snout to the posterior margin of the vent. To reduce bias, one of us (LJW) measured all subjects. We determined the amount of time (± 0.1 sec.) required for each measurement to evaluate the efficiency of the three methods. We completed all measurements over a five-day period and released salamanders at their capture site.

We determined measurement precision using the coefficient of variation (CV; Zar 1999). Salamanders have a tendency to contort their bodies when manipulated (Wise and Buchanan 1992), often reducing their body lengths. Because of this tendency, we assumed that the method providing the smallest mean SVL would be the least accurate representation of the "true" SVL. In contrast, the most accurate method should provide the greatest mean SVL. The precision and accuracy of each method were analyzed using one-way analyses of variance (ANOVA). All data conformed to assumptions of parametric statistics and analyses were conducted using SPSS 12.0 (SPSS, Inc. 2003).

There was a difference in the mean SVL ($F_{2,59} = 5.79$, $P = 0.005$) and CV ($F_{2,59} = 5.75$, $P = 0.005$) among the three measurement methods (Table 1). Bonferroni post-hoc tests indicated that measuring salamander SVL with the Salamander Stick was more accurate and precise than the Freehand and Tube methods. The Freehand and Tube methods did not differ in precision or accuracy. While our results obtained from the Tube and Freehand methods do not differ, neither method was more accurate or precise than the Salamander Stick. This is likely because the Tube and Freehand methods do not restrict salamander movement and straighten its vertebral column as well as the Salamander Stick. As another testament to its efficiency, we found that the Salamander Stick allowed measurements to be obtained with the least time expended (Table 1). Other techniques to obtain salamander measurements may not be as efficient as the Salamander Stick. For instance, using a plastic sandwich bag alone (without the stick) is another method used to immobilize salamanders and obtain morphometric measurements ("Baggie" method; Bury and Corn 1991). Although we did not compare the Baggie method and the Salamander Stick, we suspect that the PVC pipes decrease the time spent measuring individuals and the likelihood that a subject will contort its body as the measurement is taken.

FIG. 1. The Salamander Stick, a device for obtaining precise and accurate measurements of salamander snout–vent length. A) The device shown with a plastic bag passing through the gap between the two polyvinyl chloride (PVC) pieces. B) The lateral view of an adult Smallmouth Salamander (*Ambystoma texanum*) immobilized in the device.

TABLE 1. Accuracy (mean SVL ± 1 SE) and precision (CV ± 1 SE) for 20 Smallmouth Salamanders (*Ambystoma texanum*) measured by the three methods in March 2004. Measurement time (sec, mean ± 1 SE) is the amount elapsed between initially manipulating the salamander and the moment at which the measurement was obtained.

Method	Mean SVL (mm)	CV%	Time (s)
Freehand	76.7 ± 1.3	4.2 ± 0.4	56.5 ± 4.0
Tube	77.9 ± 1.5	4.4 ± 0.4	37.0 ± 1.3
Salamander Stick	82.7 ± 1.2	2.7 ± 0.3	34.7 ± 1.2

The Salamander Stick is an accurate, precise, and time-efficient method for obtaining standardized salamander measurements. The device is simple in design, durable, and easily transported and used in the field. It can be used to measure salamander SVL as well as total length, and the width of the device is easily modified to accommodate salamanders of different sizes including large larvae (> 3 mm girth) or neotenic species. It is inexpensive, costing less than US $6.00 to manufacture. The plastic sandwich bags used in measurements can be replaced after wear and can be easily cleaned. We have used this device in the field to measure breeding adult *A. texanum* in the spring of 2004 (N = 986), without any injury to the study organisms. Similarly, we witnessed no ill effects of repeated use of this device on the salamanders measured in this study.

Acknowledgments.—Salamanders were handled with approval from the Eastern Illinois University Institutional Animal Care and Use Committee. We sincerely thank M. Walston for assistance with data collection; and J. Florey, S. Klueh, V. Millhoff, and M. Sikich, and three anonymous reviewers for comments on a previous draft of this manuscript.

The skink *Carlia ailanpalai* is introduced (Zug 2004) on the southernmost islands of the Mariana archipelago (Guam, Rota, Tinian, and Saipan) and reaches dense populations on Guam (mean population estimate of 9150 *Carlia*/ha for certain areas; Campbell 1996). It is likely that the species was introduced in the late 1950s to early 1960s (McCoid 1993, 1999). On Guam, the species is medium-sized and exhibits a negligible sexual dimorphism in size (males reach at least 63 mm and females 62 mm SVL) and in coloration (both sexes have a uniform light brown dorsum with cream venter grading to a slight peach on the ventral aspect of the tail). It has been suggested that C. *ailanpalai* might negatively impact native scincids (McCoid 1995, 1997). The biology of *C. ailanpalai* has not yet been reported.

We are unaware of information on long-term captive maintenance of small Australasian scincids. Available information on captive maintenance of small scincids comes from short-term studies on behavior (Done and Heatwole 1977; Perrill 1980; Torr and Shine 1994; Whittier 1993; Whittier and Martin 1992; Zwickel and Allison 1986).

As part of a larger study on the colonization biology and interactions of two western Pacific skink species (*C. ailanpalai* and *Emoia caeruleocauda*), we established a colony of these species in Kingsville, Texas. We maintained this colony for approximately 20 months until we voluntarily ceased observations. On 30 June 1995 we received 14 adult *C. ailanpalai* (6 male: 8 female; 45–55 mm SVL) and 10 subadult to adult *E. caeruleocauda* (5 male: 5 female; 35–45 mm SVL) from Guam, Mariana Islands. Observations on captive maintenance of *E. caeruleocauda* are presented elsewhere (McCoid et al. 1997). Size at maturity was determined by the presence of secondary yolking follicles revealed by dissection of preserved material (McCoid 1997). Sexes can be easily distinguished as adult males have a markedly swollen tail base. Initially, all *C. ailanpalai* were housed in a single 75 L (20 gal) aquarium. This aquarium had a sand substrate with three flat rocks for basking and cover. A shallow water dish was placed in the tank along with a small potted ivy plant (*Pothos* sp.). The aquarium was kept in a curtained, secluded room and supplied with fluorescent lighting set in an aquarium reflector. The room was air-conditioned and daily air temperatures in the aquarium ranged between 20 and 32.2˚C while daily humidity ranged between 60 and 90%. Crickets were fed twice weekly and we maintained the *C. ailanpalai* under these conditions for approximately nine months. There was no mortality during this period.

Beginning in Apri1 1996, for the next seven months of this study, we divided the 14 lizards into four 75 L (20 gal) screen-covered aquaria. Two females were placed in each tank and two males in two of the tanks. The remaining two tanks each received a single male. A 50:50 mixture of potting soil and sand was provided as a substrate and a potted ivy plant was placed in each tank. Several small flat rocks were placed in each tank as cover and basking sites. A small shallow tray in each tank was kept filled with distilled water and tanks were hand-misted twice daily. Approximately once a week, about 0.5 L of distilled water was poured into the substrate. A 300 ml dirt-filled rectangular Tupperware, container with a hole cut in the top was supplied as an egg-laying chamber. We replaced the 48-inch fluorescent lamp with a full-spectrum Vita-Lite fluorescent lamp (Duro-Test Corp.) set in a reflector and installed an additional 50 W basking-lite heat lamp (Duro-Test Corp.). The heat lamp was suspended within the aquarium ca. 20 cm above the substrate and over a basking rock. Heat lamps and fluorescent lamps were turned on at 0700 h. At 1000 h, heat lamps were turned off. At approximately 1800 h heat lamps were turned on again and left on until 1900 h when all illumination was discontinued for the evening. Daily temperatures ranged between 20 and 32.2˚C with the basking spot under the heat lamp reaching 55˚C.

Throughout the study period, the photo regime was kept at 12L: 12D to approximate conditions on Guam (which vary seasonally between 13L: 11D and 12L: 12D). Lizards were fed *ad libitum* with crickets every other day. Two feeding regimens were attempted. Initially, for the first week, crickets were dusted with Tetra® Reptical calcium/vitamin powder but all lizards refused ‘white’ crickets. In order to provide the lizards with a vitamin supplement, for the remainder of the study, we then fed the crickets powdered (prepared with a coffee grinder) T-Rex® Calcium Plus cricket food, essentially ‘gut-loading’ crickets with nutrients

and calcium. Crickets also were fed dry oatmeal and given water *ad libitum*. The 14 *C. ailanpalai* would consume ca. 1000 two- to three-week-old 'gut-loaded' crickets in 10 days.

In November 1996, we combined the remaining 13 (we sustained a single fatality due to an accidental rock crush) adult *C. ailanpalai* into three 75 L (20 gal) screen-covered aquaria. All other conditions mentioned previously remained the same. Captive husbandry was terminated in March 1997 and no fatalities occurred during this period.

Reproduction can be a measure of the success of captive husbandry. During the initial phase of husbandry when all 14 adults were housed in a single aquarium, only three clutches (over a nine-month span) were discovered (*C. ailanpalai* lays an invariant clutch of two, McCoid 1997). On1y one of these clutches had not desiccated and, after incubation, yielded two viable offspring. In strong contrast, the later husbandry housing configurations and feeding with nutrient-enhanced crickets yielded many more clutches. The four-aquarium configuration (eight females) produced 76 clutches over a seven-month period and the three-aquarium configuration (seven females) yielded 16 clutches over a four-month period. The total number of clutches produced over the 20-month husbandry period was 95. For individual females, intervals between clutches were computed using the four-aquarium (eight females) configuration that produced 76 clutches. Mean interval time between clutches for all eight females was 17.71 days with a range of 10–38 days.

Females seemed to repeatedly choose the same oviposition site. We recovered eggs by searching specific areas in the aquaria when gravid females were expected to oviposit. Eggs were transferred to small screw-top jars containing a dampened paper towel folded to fit the bottom of the jar. The jar lid was lightly fastened and the jar was placed in a darkened room (daily temperature range 21–32°C). Incubation periods (34–35 days) were identical to those reported by McCoid (1994) for wild-collected eggs. With the exception of the initial two desiccated clutches, all clutches were fertile and hatched. A single clutch from the three-aquarium configuration had viable, but malformed offspring.

The eight P generation females produced a total of 186 viable hatchlings during the 20-month study. Just prior to the termination of this study, we hatched the first F2 generation. We noted no decline in fecundity of the P generation through time and our results suggest that the Fl generation was healthy and fertile. Since the original lizards received from Guam were adults and all survived 20 months (with the exception one individual), we can assume that the species can live a minimum of two to three years in captivity. This adult longevity, coupled with ease of maintenance, high fecundity, and hatchling survivorship, suggests that this species might be a candidate for large-scale breeding efforts for those requiring large numbers of lizards.

This information also suggests reasons for success as colonizers in the southern Mariana Islands.

Acknowledgments.—Craig Clark aided in obtaining the lizards on Guam. Gary Padawer (Duro-Test Corp.) was helpful in the formative stages of this study. Hugh McCrystal gave us the benefits of his reptile husbandry experience. The Biological Resources Division of the USGS, Contract 14-45-0009-94-1025, and the Caesar Kleberg Wildlife Research Institute funded portions of this study.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 36, Number 1 (March 2005).

CAUDATA

AMBYSTOMA MACULATUM (Spotted Salamander). **REPRODUCTION**. Baseline phonological and reproductive success information on amphibian species is important in determining the decline, stability, or increase in population. Herein we document the reproductive life history of the spotted salamander from seven breeding ponds and vernal pools (3 permanent beaver ponds fed by small streams, 3 vernal pool complexes, and 1 ephemeral stream) during the 1999 breeding season. All of these breeding pools are found with the confines of Powhatan Lakes Wildlife Management Area, in Powhatan County, Virginia, USA. The first adult discovered in or near one of the seven breeding areas was on 16 February. This animal was dead, possibly frozen the night before. There was no sign of predation or scavenging. Spermatophores were first observed in breeding pools on 21 February. Egg masses were discovered three days later. Egg masses discovered in breeding pools were counted, flagged, and tracked for hatching success over the course of the breeding season. Each breeding pool was checked at least three times per week. Egg deposition lasted over a period of 50 days (24 Feb–14 April). Number of eggs per mass ranged from 8 to 177 (mean ± SD = 71.9 ± 35.4, N = 158). The depth (cm) egg masses were deposited ranged from 0 – 23 (4 ± 3.8, N = 99). The mass (g) of the wet swollen weight of the egg masses ranged from 10 to 380 (111 ± 68, N = 140). The percent of eggs hatching ranged from 0 to 100 (89 ± 23.6, N = 93). Fungal hyphae were seen covering dead embryos under microscopic examination, even in intact egg masses. It is not known if this was the cause of mortality or just normal decomposition. All but one egg mass were of the clear jelly type, N = 140. Masses were found attached to various substrates at the following rates: blades of grass (43 masses), submerged sticks (37), hardwood leaves (*Acer rubrum, Fagus grandifolia, Liquidambar styraciflua, Quercus alba, Q. falcata, Q. palustris, Q. rubra*, and *Salix* sp.) (34), unattached (34), underwater plant stems (not grass) (5), *Juncus* sp. (4), metal flagging pole (1), *Carex* sp. (1), N = 159. Twenty-one percent of the egg masses were unattached to substrate. This strategy may help in the survival of this species in ponds and ephemeral breeding areas that dry up early. The last adult spotted salamanders found at breeding pools was on 28 April.

AMBYSTOMA MACULATUM (Spotted Salamander). **PREDATION.** The known predators of *A. maculatum* include aquatic invertebrates and several vertebrates (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, DC.). Petranka (1998. *op. cit.*) listed only one bird as a predator of *A. maculatum*, the least sandpiper (*Calidris pusilla*), which was observed feeding on the larvae of *A. maculatum* (Stangel 1988. Herpetol. Rev. 14:112). Here I report an adult female Common Grackle (*Quiscalus quiscala*) preying on a partially exposed *A. maculatum* egg mass in a vernal pool on 15 May 2004 at 1320 h. The vernal pool, dominated by a button bush (*Cephalanthus occidentalis*) scrub association, was located at ca. 20 m elev in Willowdale State Forest, Town of Ipswich, Essex County, Massachusetts USA (42.68379°N, 070.90342°W). The egg mass had been deposited earlier in the season (likely late March) on a fully submerged button bush branch.

Peer and Bollinger (1997. The Birds of North America, No. 271. Acad. Nat. Sci. Philadelphia, Pennsylvania and American Ornithologists' Union, Washington, DC), state that the Common Grackle is an opportunistic forager. Among the small vertebrates taken, Peer and Bollinger (1997, *op. cit.*) listed salamanders, having cited Hamilton (1951. Auk 68:213–217), who determined over a two-year period that salamanders were an important dietary component of common grackles in central New York, especially in the food brought to their nestlings. The grackle that I observed feeding on salamander eggs was one of several observed foraging amongst the button bush and cattail (*Typha latifolia*) growing in the pond. The grackle was observed for a only a short time before my presence likely disturbed it while it was feeding on the eggs, plucking and consuming several from the exposed part of the egg mass above waterline. The grackle appeared to be undeterred by the gelatinous outer coating of the Spotted Salamander's egg mass, which has been shown to protect against predation and desiccation (Nyman 1987. Herpetol. Rev. 18:15). Common Grackles were observed nesting in the area and it is possible that the grackle I observed feeding on the Spotted Salamander eggs was out gathering food for one or more of its nestlings. No other grackles or other birds were directly observed feeding on other similarly exposed egg masses in the area. To my knowledge this is the first observation of a bird feeding on the eggs of *A. maculatum*, and it might also represent the first record of a bird feeding on the eggs of any salamander.

The Massachusetts Division of Fisheries and Wildlife funded this work. Jonathan Regosin administered the work. I thank Mark Grgurovic, Department of Natural Resources and Conservation, University of Massachusetts, Amherst, who supervised all fieldwork and Jacob Kissel who assisted in the field.

AMBYSTOMA MACULATUM (Spotted Salamander). **PREDATION.** Since 1999, annual surveys have been conducted at 46–70 vernal pools in New London County, Connecticut USA. These surveys are conducted to quantify *Ambystoma maculatum* and Wood Frog (*Rana sylvatica*) egg masses as well as to document the presence of fairy shrimp and Marbled Salamander (*A. opacum*) larvae. From 1999 to 2003, no Snapping Turtles (*Chelydra serpentina serpentina*) were observed during these surveys. While conducting surveys in 2004, however, I observed 7 snapping turtles in 5 different vernal pools over four days. I witnessed both direct

and indirect signs of Snapping Turtles feeding on salamander eggs.

While conducting egg mass surveys on 18 April 2004, I observed a large (ca. 400 mm carapace length) Snapping Turtle submerged in the water of a pool. The turtle had Spotted Salamander eggs hanging out of its mouth and small fragments were floating in the vicinity of the turtle's head. The snapping turtle did not move when I approached. No other intact egg masses were observed in the vicinity of the turtle. On 19 April, I observed a Snapping Turtle (ca. 300 mm carapace length) floating near a large conglomeration of egg masses in another vernal pool. As the turtle approached me, small fragments of Spotted Salamander eggs were observed floating in the vicinity of the turtle. On 19 April and 21 April, I observed two additional Snapping Turtles (ca. 420 mm and 100 mm carapace lengths) in two vernal pools. No predation on eggs was observed. On 20 April, I observed three Snapping Turtles in a small vernal pool. The estimated carapace lengths of these turtles were 100, 330, and 420 mm. Although no turtles were observed eating eggs, fragments of Spotted Salamander egg masses were observed floating throughout the pool.

Although Snapping Turtles are not usually associated with vernal pools, it has been reported that adults prefer permanent bodies of water whereas younger individuals (150–250 mm carapace length) may be found in vernal pools (Klemens 1993. Amphibians and Reptiles of Connecticut and Adjacent Regions. State Geological and Natural History Survey of Connecticut. Bull. No. 112). Aquatic plants and fish were the major food items in the stomachs of 470 snapping turtles collected in Connecticut (Alexander 1943. J. Wildl. Manag. 7:278–282). I found no previous reports of Snapping Turtles eating Spotted Salamander egg masses.

AMPHIUMA MEANS (Two-toed Amphiuma). **PREDATION.** Known avian predators of *Amphiuma means* include various large wading birds (Dye 1982. Florida Field Nat. 10:76; Kilham 1984. Colonial Waterbirds 7:143–145). At 2350 h on 11 June 2004, I observed an adult Barred Owl (*Strix varia*) subduing a prey item in a shallow roadside ditch (floodplain of Drowning Creek, 3.5 km N of Hoffman, Richmond County, North Carolina, USA). The owl's legs were immersed in several cm of water and its wings were spread for balance as it struggled with the unidentified prey. I exited my vehicle and shone a flashlight on the owl, which presently hopped from the water onto the ditch bank, striking with its bill at an object held in its talons. I was able to approach to within a few meters and identify the prey as a small *A. means* (ca. TL 30–40 cm). After several seconds, the owl flew into a nearby tree with the amphiuma and apparently finished killing it there before carrying it out of my view into thick woods. Barred Owls are opportunistic predators, known to take a wide range of terrestrial and aquatic prey, including various amphibians (Bent 1938. Life Histories of North American Birds of Prey, Part II. Dover Publishing, Inc., New York, NY. 482 pp.). To my knowledge, this represents the first record of predation on *A. means* by an owl.

DICAMPTODON ATERRIMUS (Idaho Giant Salamander). **REPRODUCTION.** The natural history of *Dicamptodon aterrimus*, whose distribution is limited to the Northern Rocky Mountains of Idaho, is poorly known (Nussbaum et al. 1983. Amphibians and Reptiles of the Pacific Northwest. Univ. Idaho Press, Moscow.). On 20 June 2004, we visited Mountain Gulch, a tributary of the North Fork of the Palouse River in Latah County, Idaho (47°01'N, 116°31'W). At ca. 1330 h, we located a clutch of ca. 20–30 white eggs attached to the lower surface of a large, flat rock submerged in about 15 cm of relatively slow-moving water. No obvious signs of embryonic development were apparent, suggesting that the eggs had been laid recently. A *D. aterrimus* (109 mm SVL) was associated with the clutch, and we assumed her to be a brooding female. The presence of distinct gills indicates that this individual was paedomorphic. We know of no other direct observations that indicate breeding by paedomorphs in *D. aterrimus*.

PLETHODON ALBAGULA (Western Slimy Salamander). **VOCALIZATION**. Several species of salamanders are known to vocalize (Brodie 1977. Copeia 1977:523–535; Brodie 1978. Copeia 1978:127–129; Davis and Brattstrom 1975. Herpetologica 31:409–412; Duellman and Trueb 1994. Biology of Amphibians. John Hopkins Univ. Press. Baltimore, Maryland. 670 pp; Mansutei 1941. Copeia 1941:266–267; Marshall 1997. Herpetol. Rev. 28:145; Neill 1952. Copeia 1952:195–196; Smith and Barichivich 2001. Herpetol. Rev. 32:246–247; Wyman and Thrall 1978. Herpetologica 28:210–212). The few sounds noted have been correlated with defense and anti-predatory behavior (Davis and Brattstrom 1975, *op.cit.*). *Plethodon albagula* has not been documented to vocalize. The following describes vocalization in five *P. albagula* adult females.

An abandoned mineshaft in Garland County, Arkansas USA, was visited between 27 June and 1 Aug 2004 and 122 adult *P. albagula* were captured. All animals were taken along the walls inside the mineshaft; air temperature was 16°C. On 27 June 2004, 122 adults (114 females and eight males) were photographed and placed in a plastic bag to be sexed and measured. On 17 and 18 July 2004, 79 animals (77 females and two males) were photographed and placed in a plastic bag to be sexed, measured, weighed, and injected with subcutaneous fluorescent Visual Implant Elastomer (VIE) markings (Northwest Marine Technology Inc., Shaw Island, Washington). None was injected more than two times, and 8 had been previously injected (all females); therefore, these salamanders underwent an abbreviated handling process.

Vocalizations were observed on 27 June and 17–18 July 2004. On 27 June between 1200 and 1900 h, vocalizations were wit-

nessed in an undocumented number of animals as a series of chirping noises. The chirping noises were audible enough to be heard 5–7 m away and greatly resembled the sound of a cricket. The vocalizations were also observed and documented on 17 July between 1100 and 1600 h by three adult females. The sounds were identical to the previous noises on 27 June. Of the three females heard vocalizing, one female (62 mm SVL) was gravid and had undergone the entire handling process including the injection of two VIE marks. Another female (55 mm SVL) was not gravid and also underwent the entire handling process, and one non-gravid female (59 mm SVL) was injected on 26 Oct 2001, but still underwent the handling process. This female was also captured on 1 Aug 2004 and did not vocalize. On 18 July 2004 between 0900 and 1200 h two more females were noted producing the noise. Both females had undergone the entire handling procedure. One female (64 mm SVL) was gravid and the other (69 mm SVL) was not gravid. In all cases, the salamander's mouth was closed; however, their gular region was pulsating. It is unclear whether the pulsating of the throat was related to the vocalization. All sounds were repetitive and stopped after a few seconds. In all but one case, in which the animal produced the sound while in a plastic bag, the vocalizations were observed after the animals were released and did not appear to be associated with any defense posture or behavior.

The function of the chirping noise is unknown. The noises were only observed in females; however, only a small number of males were handled (N = 10). This behavior apparently was not an anti-predatory response. The simple handling of the salamanders may have elicited the sound production. The injection of fluorescent VIE was probably not the stimulus for the noise, as one individual was not injected prior to the vocalization. This population of salamanders has been handled on a number of occasions in the past, but no other observations of vocalization have been recorded.

The chirping noises might be used as a warning, as the vocal salamanders were in close proximity. Two were within 3 m of each other, and two were within 9 m; in every instance, each produced the noise after they were handled. Furthermore, a non-gravid female (captured and injected on 26 Oct 2001), vocalized on 17 July 2004, but did not vocalize 1 Aug 2004 after being handled once again. Brodie's (1978, *op. cit.*) suggestion that vocalization was a means of warning predators of noxious skin secretions might have support in this instance. Every *P. albagula* handled secreted a sticky discharge. Further studies on vocalization as a means of warning in Plethodontidae are warranted.

We thank the United States Forest Service for funding and Brian Caldwell for field assistance.

Submitted By **JOSEPH R. MILANOVICH** (e-mail: joseph.milanovich@smail.astate.edu) and **STANLEY E. TRAUTH,** Department of Biological Sciences, P.O. Box 599, Arkansas State University, State University, Arkansas 72467, USA.

PLETHODON CINEREUS (Eastern Red-backed Salamander). **EARLY NESTING.** Breeding in *Plethodon cinereus* is either annual (southern populations) or biennial (northern populations) (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington, DC. 587 pp.). Females typically oviposit an egg cluster in late spring or early summer, although rare late summer oviposition may occur, and the females remain with the eggs during their developmental period (Bishop 1941. New York St. Mus. Bull. 324:1–363, Petranka 1998, *op. cit*.). In Virginia, Eastern Red-backed Salamanders typically nest in June (Martof et al. 1980. Amphibians and Reptiles of the Carolinas and Virginia. Univ. North Carolina Press, Chapel Hill. 264 pp.), but Ernst et al. (1997. Bull. Maryland Herpetol. Soc. 33:1–62) reported oviposition in northern Virginia from late May to June (25 May–10 June, unpubl. data).

On 7 April 2004 at 1420 h, we found a female, lead-backed morph *P. cinereus* coiled over an egg cluster under a large wooden tie at the edge of an open mesic woodland at the Mason Neck National Wildlife Refuge, Fairfax, Virginia. Six eggs were exposed, but the female was reclining on several additional eggs. The egg cluster was directly on the soil under the tie.

This is the earliest recorded date for oviposition in *Plethodon cinereus*.

Submitted by **JOHN M. ORR** and **CARL H. ERNST** (e-mail: motherbox2@aol.com), Division of Amphibians and Reptiles, MRC 162, Smithsonian Institution, P.O. Box 37012, Washington, DC 20023-7012, USA.

PLETHODON CINEREUS (Eastern Red-backed Salamander). **PREDATION.** The Creek Chub, *Semotilus atromaculatus* (Cyprinidae), is a common inhabitant of forested streams and is broadly sympatric with the Eastern Red-backed Salamander, *Plethodon cinereus*.

On 11 July 2003 in Boston Run (Summit County, Ohio, USA), we captured an adult *S. atromaculatus* that had ingested an adult *P. cinereus.* The creek chub had a standard length of 166 mm, a total length of 170 mm, and a wet mass of 54.7 g. The *P. cinereus* was partially digested and in generally poor condition, thus we measured its length from the snout to base of the hind limb, following Szuba et al. (2002. Herpetol. Rev. 33:187–189). Snout to base of hind limb length was 35.9 mm. Dissection of the *P. cinereus* revealed the following stomach contents: one mite (Acari: Oribatida), fly wings (Diptera: Ceratopogonidae and Sciaridae), and segments of at least 13 ants (Hymenoptera: Formicidae).

Throughout the Boston Run watershed, we have found numerous *P. cinereus* under woody cover and in the leaf litter of small ravines that only carry water during periods of heavy rain. The *P. cinereus* discussed within this note was likely washed into the stream during severe storms that resulted in flash floods throughout the region. This hypothesis is supported by the terrestrial nature of the stomach contents of the salamander.

To the best of our knowledge, this is the first published report of *S. atromaculatus* consuming an adult terrestrial salamander as well as the first report of *P. cinereus* being preyed upon by a fish.

This research was conducted at the Woodlake Environmental Field Station within the Cuyahoga Valley National Park. The Cuyahoga Valley National Park provided the necessary permits to conduct this research, and we are grateful for their continued support. Funding for this work was provided through the National Science Foundation Research Experiences for Undergraduates program.

TARICHA TOROSA TOROSA (Coast Range Newt). **OVERWINTERING LARVAE.** We present observations of overwintering behavior in *Taricha torosa torosa* larvae at two independent sites. We define overwintering larvae as newts that spend the entire winter season in the larval form. The winter season (December, January, and February) represents the average three coldest months for the southern California coastal region (Felton 1965. California's Many Climates. Pacific Books. 169 pp.).

From Dec 2001 through July 2002, daytime and/or nocturnal visual encounter surveys were conducted in pools in Adobe Creek (Santa Rosa Plateau Ecological Reserve, Murrieta, Riverside County, California USA) at least once per month for a phenology study of *T. t. torosa*. Larval *T. t. torosa* were captured with a dipnet, measured, and on occasion voucher specimens were collected. (Preserved specimens are currently in the collection of US Geological Survey, Biological Resource Discipline, San Diego Field Station [RNF]).

On 25 April 2001, breeding adults and over 50 egg masses were observed in a pool in Adobe Creek. In addition to the breeding activity, three *T. t. torosa* larvae (37–40 mm TL) approaching the size for metamorphosis (50–60 mm TL) (Bishop 1943. A Handbook of Salamanders. Comstock Publishing. 555 pp.) were also captured and examined. Most notable is the considerable size of the three premetamorphic larvae in comparison to the average size of recently hatched *T. t. torosa* larvae at 11–12 mm (Bishop 1943, *op. cit*.). We recognized the three large larva present at the commencement of the 2001 breeding season as larvae from the previous year that spent the winter season in the larval form, hence overwintered.

On 01 May 2002, a single larva collected measured 53 mm TL and was found in a pool containing breeding adults and egg masses (voucher number: RNF 2552). However, during the previous year egg masses were only observed on Adobe Creek in April and May. Consequently, cohorts of the April/May 2001 embryos should have transformed sometime between early Aug and mid Dec 2001(based on the natural history of *T. t. torosa*) if growth and development had not been delayed during the fall and winter months (see Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press. 587 pp.). We recognize the large larva (53 mm TL) present at the commencement of the 2002 breeding season as a larva that overwintered.

While conducting a review of the published literature we came across only one previous report of overwintering *T. t. torosa* larvae (Storer 1925. Univ. California Publ. Zool. 27:1–342).

Our recent observations of overwintering *T. t. torosa* larvae reported herein and Storer's (1925, *op. cit.*) historical record represents observations from two locations separated by a distance of ca. 90 km. Despite the documentation of two consecutive years of overwintering *T. t. torosa* larvae on Adobe Creek, we suspect this phenomenon does not occur often because of the paucity of previous reports or published records (Jennings and Hayes 1994. Amphibian and Reptile Species of Special Concern in California. Final Rept. to California Dept. Fish and Game. 225 pp.; Petranka 1998, *op. cit.*; Storer 1925, *op. cit.*).

Our thanks to Carol Bell of The Nature Conservancy for permission to work on the Santa Rosa Plateau Ecological Reserve, and Norman J. Scott and Kathie P. Meyer for useful comments. Permission to handle and collect specimens was granted under California Department of Fish and Game permits SC-005428 and SC-000838, and MOU.

ANURA

AMOLOPS CREMNOBATUS (Rough-backed Torrent Frog). **ENDOPARASITES.** *Amolops cremnobatus* was described from specimens collected in Khammouan Province, Laos (Inger and Kottelat 1998. Raffles Bull. Zool. 46:29–34) and was reported in Vietnam by Bain and Truong (2001. Herpetol. Rev. 32:269). To our knowledge there are no reports of endoparasites from this species. The purpose of this note is to report the nematode *Falcaustra trilokiae* from *A. cremnobatus.*

Three *A. cremnobatus* (SVL 33 mm ± 3 mm SD, range: 29–35 mm) were collected 21 April 1999 from Ha Tinh Province, Huong Son District (18°20'N, 105°14'E), Vietnam and deposited in the herpetology collection of the Natural History Museum of Los Angeles County, Los Angeles, California as LACM 146884–146886. The esophagus, stomach, small intestine, large intestine, lungs and urinary bladder were opened and examined separately for helminths under a dissecting microscope. The body was also searched. Each frog was found to harbor individuals of Nematoda in the small or large intestines. The nematodes were cleared in a drop of concentrated glycerol, identified as *Falcaustra trilokiae*, and deposited in the United States National Parasite Collection, Beltsville, Maryland as USNPC 94898. Prevalence of infection (number infected frogs/number frogs examined) × 100 and mean intensity of infection (mean number of infected individuals) ± 1 SD and range were: 100%, 4.3 ± 3.2, 2–8.

Falcaustra trilokiae was originally described from specimens taken from *Euphlyctis cyanophlyctis* (Ranidae) collected in Andhra Pradesh State, India (Singh 1958. J. Helminthol. 32:132–138). *Amolops cremnobatus* represents the second host for *Falcaustra trilokiae.* Vietnam is a new locality record.

We thank Robert F. Inger (Field Museum of Natural History, Chicago, Illinois) for identification of *A. cremnobatus* and Amanda Woolsey (Whittier College) for assistance with dissections.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb@psu.edu).

ATELOGNATHUS PATAGONICUS (NCN). **PREDATION**. Various species prey on larval and post-metamorphic anurans, such as spiders, aquatic insects, fishes, birds, and mammals (Duellman and Trueb 1994. Biology of Amphibians. The Johns Hopkins Univ. Press, Baltimore. 670 pp. and references therein). *Atelognathus patagonicus* is a leptodactylid occurring in Laguna Blanca National Park and the surrounding area of Neuquén Province, Argentina. This frog is highly adapted for aquatic life with enlarged interdigital membranes and lateral and ventral skin folds (Cei and Roig 1968. Physis 27:265–284; Duellman and Trueb 1994, *op. cit.*). The species is listed as endangered in Argentina (Lavilla et al. 2000. Categorización de los Anfibios y Reptiles de la República Argentina. Asociación Herpetológica Argentina. 97 pp.). The habitat of *A. patagonicus* is semi-permanent to permanent ponds and lakes. Numerous species of aquatic and semi-aquatic birds also live at these sites.

We report field observations of predation on *A. patagonicus* by four species of birds. During a survey along the northwest shore of Laguna Verde—a permanent pond of 0.17 km^2 (39°0'S, 70°23'W; 1282 m elev.) in Laguna Blanca Park—we observed predation by the Silvery Grebe (*Podiceps occipitalis*) and the White-tufted Grebe (*P. rolland*) on tadpoles and post-metamorphic *A. patagonicus*. Between 1120 and 1220 h on 28 Dec 2003, we observed 22 captures by the birds. Seven Silvery Grebes captured 6 tadpoles and 15 post-metamorphic frogs. One White-tufted Grebe captured one post-metamorphic *A. patagonicus*. We watched individual birds and could track the number of prey consumed by each one. During these observations, one bird caught three *A. patagonicus*. A grebe would dive underwater, for as long as two minutes, and then emerge with a prey item in its beak. Birds held the tadpoles by their tails and the frogs by one of their legs. Then the bird would slap the prey against the water surface before swallowing it head first. We observed similar acts of predation by these two species on 29 and 30 Dec 2003, between 900 and 1700 h. At Laguna el Hoyo—another permanent pond in the national park—two other birds, the Brown-hooded Gull (*Larus maculipennis*) and the Andean Ruddy Duck (*Oxyura ferruginea*), were observed preying on *A. patagonicus* on 15 Jan 2002. In these two lagunas the most common predators are birds, and they can capture at least three frogs per hour. Hence, it is important to fully understand the interaction between bird predation and *A. patagonicus* populations.

This work was supported by Rufford Small Grant (for nature conservation) in association with the Whitley Lain Foundation and Wildlife Conservation Society Research fellowship.

BUFO AMERICANUS (American Toad) and ***RANA CATESBEIANA*** (Bullfrog). **MICROHABITAT**. Use of burrows by amphibians has been documented for several species. During a field study, adult *B. americanus* (21 April 2001) and juvenile *R. catesbeiana* (9 March 2002) were observed using crayfish burrows at a breeding pond in Union City, Madison County, Kentucky. Use of burrows occurred as the pond was receding during dry conditions, suggesting burrows may have been used as refugia to avoid desiccation.

BUFO AMERICANUS CHARLESMITHI (Dwarf American Toad). **MAXIMUM SIZE**. Conant and Collins (1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. Third Ed., Expanded. Houghton Mifflin, Boston. 616 pp.) report the record size for *Bufo americanus charlesmithi* as 6.4 cm. Herein, we report on a new maximum body size for this subspecies from Arkansas.

On the night of 17 April 2004, we collected an adult female *B. a. charlesmithi* crossing St. Hwy 88, ca. 0.2 km W Queen Wilhelmina State Park, on the top of Rich Mountain (Polk County; 34°41.240'N, 94°23.143'W; elev. 768 m). The specimen measured 10.2 cm SVL at the time of preservation on 20 April 2004 and 9.5 cm SVL upon a more recent measurement on 14 June 2004.

The specimen was deposited in the Arkansas State University Museum of Zoology herpetological collection (ASUMZ 28453) and collected under the authority of an Arkansas Game & Fish Commission scientific collection permit.

BUFO MARINUS (Cane Toad). **PREDATION**. *Bufo marinus* is a widespread anuran native to central and tropical South America that has been introduced into several other countries for pest control (Easteal 1981. Biol. J. Linn. Soc. 16:93–113). In these countries, the uncontrolled expansion of *B. marinus* is causing a negative impact upon native species (Catling et al. 1999. Wildl. Res. 26:161–185). Although it has been documented that eggs and tadpoles are toxic to a wide range of aquatic predators including invertebrates, fish, and other anurans (Crossland and Azevedo-Ramos 1999. Herpetologica 55:192–199; Punzo and Lindstrom 2001. J. Herpetol. 35:693–697), there is little information about natural predators of larval stages of this species (Hutchings 1979. N. Queensland Nat. 45:4–5; Crossland 1998. Herpetologica 54:364–369). Snakes of the genus *Liophis* inhabit mesic habitats and their diet consists largely of anurans and their larvae. At least one species, *L. epinephelus*, feeds on *B. marinus*, and *L. melanotus* has been reported as a predator of *Bufo granulosus* (Michaud and Dixon 1989. Herpetol. Rev. 20:39–41). On 18 Feb 2004 near Chichiriviche, Vargas State, Venezuela (10º32'N, 67º14'W, 135 m elev.), we observed an adult male *L. melanotus* on the shore of the Río Chichiriviche, 3 km SW of Chichiriviche, in a shallow margin of the river that was also occupied by a few hundred *B. marinus*

tadpoles. When captured, the snake regurgitated 8 large *B. marinus* tadpoles that appeared to have been recently swallowed. Voucher specimens are deposited in the Museo de La Estación Biológica de Rancho Grande (EBRG), Ministerio del Ambiente y de los Recursos Naturales, Venezuela as EBRG 4460 (*L. melanotus*) and EBRG 4939 (*B. marinus* tadpoles).

BUFO OCELLATUS (NCN). **DEATH FEIGNING**. Death feigning or thanatosis (Edmunds 1974. Defense in Animals. Longman, New York, 357 pp.), is a common behavior among frogs (Sazima 1974. J. Herpetol. 8:376–377; Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill, New York; Azevedo-Ramos 1995. Rev. Bras. Biol. 55: 45–47). On 7 Aug 2003, in Unaí Municipality (46°7'W; 16°9'S) when handling an adult male *Bufo ocellatus* (42.8 mm SVL), I observed death feigning behavior in this species. The specimen adopted a motionless posture, keeping his limbs close to the body and eyes closed. After 45 sec. in this position, the frog started moving, attempting to escape. However, when restrained it reinflated the lungs and released bladder liquid. Both behaviors are similar to those described for *B. paracnemis* (Zamprogno et al. 1998. Herpetol. Rev. 29:96–97) and probably are widespread among other species of this genus. The function of death feigning might be related to increasing the chances of being lost by a predator and/or to minimization injuries when seized by a predator (Sazima, *op. cit*.). A voucher specimen (AAG-UFU 2484) is housed in the Museu of Biodiversidade do Cerrado, Universidade Federal de Uberlândia, Minas Gerais, Brazil.

I thank Ariovaldo A. Giaretta for critically reading the manuscript and the owners of the Fazenda Sagres S. A. for logistic support.

Submitted by **MARCELO N. DE C. KOKUBUM**, Laboratório de Ecologia e Sistemática de Anuros Neotropicais, Instituto de Biologia, Universidade Federal de Uberlândia, Minas Gerais, Brazil and Programa de Pós-graduação em Ecologia, Universidade de Brasília; Brazil; e-mail: mnckokubum@hotmail.com.

BUFO PROBOSCIDEUS (NCN). **PREDATION**. *Bufo proboscideus* occurs in the Amazon River region from Ecuador to Manaus, Brazil (Frost 2002. Amphibian Species of the World: An Online Reference V2.21, April 2003). This species is diurnal, but is often seen at night when it rests off the ground on small seedlings and shrubs (Zimmerman and Bogart 1988. J. Herpetol. 22:97–108). Here, I report predation of *B. proboscideus* by the colubrid snake *Xenoxybelis argenteus*.

On 11 April 2003 (1930 h), at Reserva Florestal Adolpho Ducke (02°55'S, 59°59'W), Manaus, Amazonas, Brazil, I found a juvenile *X. argenteus* (ca. 800 mm TL) ingesting a juvenile *B. proboscideus* (35 mm SUL). At the moment of observation, only the hind limbs of *B. proboscideus* protruded from the snake. The snake was on a shrub 1.0 m above the ground and when disturbed, regurgitated the dead frog and escaped into the vegetation.

Xenoxybelis argenteus is considered to be a strictly diurnal species that sleeps on low vegetation at night (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6[2]:78–150). Their diet consists of small lizards and frogs, which are captured while the snake forages on low vegetation (Martins and Oliveira, *op. cit.*). The present observation shows that *X. argenteus* may forage opportunistically at night when frogs, such as *B. proboscideus,* sleep on vegetation.

I thank W. E. Magnusson, A. P. Lima, and D. J. Rodrigues for critically reading this manuscript; fellowship by CAPES to MM.

BUFO SPECIOSUS (Texas Toad). **MAXIMUM SIZE**. The record size reported for *Bufo speciosus* is 92 mm SVL (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. Third Ed., Expanded. Houghton Mifflin, Boston. 523 pp.). Herein, we report on a new maximum size for this species.

On 7 July 2004, a female *Bufo speciosus* was collected as we road cruised in Brewster County, Texas, USA. The toad was collected at ca. 2330 h on St. Hwy 118, 32.6 km N Terlingua. The highway was damp following a brief rain shower, air temperature was 27.8ºC. In the field the specimen measured 98 mm SVL, mass was 127 g. The specimen was deposited in the Arkansas State University Museum of Zoology herpetology collection (ASUMZ 28696). The specimen was re-measured following preservation and was 97 mm SVL. Collection of the specimen was under the authority of the Texas Parks and Wildlife Department permit (SPR-0704-398) issued to SET.

Submitted by **J. PHILLIP STEWART, WAYLON HILER, CHARLES MCDOWELL, ROBERT NEAL, BEN A. WHEELER,** and **STANLEY E. TRAUTH,** Department of Biological Sciences, Arkansas State University, State University, Arkansas 72467, USA (e-mail: strauth@astate.edu).

ELEUTHERODACTYLUS PLANIROSTRIS (Greenhouse Frog). **COLD TOLERANCE.** On 3 March 2004, a healthy adult *Eleutherodactylus planirostris* was found inside a sealed 3 cu. ft bag of cypress mulch at the Detroit Zoo, Oakland County, Michigan. According to a representative of the manufacturer this bag originated at a packing plant in Trenton, Gilchrist County, Florida 1–2 weeks prior to its arrival in Michigan on 11 July 2003. The bag was kept outside until it and several others were relocated to the zoo on 29 Jan 2004. All the bags appeared to be frozen solid at that time. The bags remained outside at the zoo until 29 Feb 2004 when the bag containing the frog was brought inside to thaw. The ability of some ectotherms to endure freezing climates results from freeze avoidance (selecting a microclimate that does not freeze), freeze resistance (supercooling), or freeze tolerance (accumula-

tion of intracellular antifreeze and nucleation of extracellular freezing) (Pinder et al. 1992. *In* Feder and Burggren [eds.], Environmental Physiology of the Amphibians, pp. 250–274. University of Chicago Press). Freeze avoidance cannot be ruled out in this case: it is possible that the bag of mulch (12 cm thick) provided a thermally protected microclimate, particularly if the bag had been ensconced within a pile of bags. Freeze resistance is not an option for amphibians due to their low supercooling capacity and water-permeable skin (Pinder et al., *op. cit.*). Freeze tolerance has been documented in certain extreme temperate amphibians, including some ranid and hylid frogs and a hynobiid salamander (Pinder et al., *op. cit.*); it has not been documented in leptodactylids. As we did not observe the frog until after the mulch had thawed, we are unable to state for certain if what we observed was freeze avoidance or freeze tolerance. However, the frog likely experienced freezing temperatures during some of its time in Michigan. During the 32 days the bag was kept outside at the zoo, maximal outdoor daily temperatures in the Metro Detroit region were below freezing on 15 days; average daily temperatures were below freezing on 23 days. *Eleutherodactylus planirostris* is native to the West Indies and has been introduced into Florida, Hawaii, Jamaica, Louisiana, Mexico (Frost 2002. Amphibian Species of the World online), and Georgia (Winn et al. 1999. Herpetol. Rev. 30:49). This species was first detected on the mainland US in southern Florida in 1875 (Cope 1875. Bull. U.S. Nat. Mus. 1:i–xi, 1–104.) and since has been spreading northward (Ashton and Ashton 1988. Handbook of Reptiles and Amphibians of Florida pt. 3, The Amphibians. Windward Publ. Inc., Miami. 191 pp.). Although it is typically thought that the northward range expansion of tropical species introduced into the southern US will be limited by cold or freezing temperatures, our observation of cold tolerance in *E. planirostris* suggests that macro-environmental temperature *per se* might not be a limiting factor for this species. Moreover, that this individual survived for ca. 8 months sealed in a bag of mulch speaks to the extreme tolerance of the species and its potential for inadvertent anthropogenic dispersal. The presence of extreme cold tolerance, or possibly freeze tolerance, in a tropical species is intriguing, especially in light of the freeze intolerance of several temperate species more closely related to freeze-tolerant species (Pinder et al., *op. cit.*), and raises questions about the origin(s) and phylogenetic distribution of the underlying physiological mechanisms.

GASTROPHRYNE OLIVACEA (Great Plains Narrow-mouthed Toad). **PREDATION**. At Yécora, Sonora, Mexico (28°22'4.0"N, 108°55'32.6"W), 1545 m, a large chorus of *Gastrophryne olivacea* was found the night of 25 July 2004, in temporary pools as much as 25 cm deep that had formed earlier that day. The chorus was an attraction for at least 3 *Thamnophis c. cyrtopsis* that were observed foraging in and around the pools. Each was watched for a time as it appeared to be directed toward one specific calling toad, none of which made any attempt to avoid the approaching snake. The head and neck of each snake were held well above the water, as though guided by vision toward the prey, although it is not likely that the snakes were attracted to the site by vision. Most pools in the area contained breeding choruses of *Hyla wrightorum* as well as *Gastrophryne*, but all snakes observed were in pools containing only the latter genus. It is possible they selectively sought the smallest anurans of the congress, which were the male *Gastrophryne*. Apparently *T. cyrtopsis* is one of the main predators of *Gastrophryne* in this area.

GASTROPHRYNE OLIVACEA (Great Plains Narrow-mouthed Toad). **REPRODUCTION**. At Yécora, Sonora, Mexico (28°22'4.0"N, 108°55'32.6"W), 1545 m, during the day on 25 July 2004 (0730–1830 h), as a light rain fell, weak, scattered calls of easily disturbed *Gastrophryne olivacea* were heard in extensive grasslands where the toads were impossible to detect, hidden in the grass and not fully emerged from their burrows. A little later an exceptionally severe, protracted rainstorm rapidly filled low areas all around town, where water accumulated in many small pools as much as 25 cm deep where none existed before. During that process emerging individual *Gastrophryne* appeared in huge numbers on almost all of the pools, where they called loudly in a low buzz lasting as long as 6 sec (as opposed to 3 sec recorded for eastern populations). Females were seen approaching the much smaller males, but they seemed to be selective, turning away at times from one male to another. Amplexus was adhesive. Eggs were laid the same night by captive specimens. Most pools were shared with *Hyla wrightorum*; only two were occupied exclusively by *Gastrophryne*.

Submitted by **HOBART M. SMITH**, Department of EE Biology, University of Colorado, Boulder, Colorado 80309-0334, USA (e-mail: hsmith@colorado.edu); **JULIO A. LEMOS-ESPINAL**, Laboratorio de Ecología, UBIPRO, Facultad de Estudios Superiores Iztacala, UNAM, Apartado Postal 314, Avenida de los Barrios 1, Los Reyes Iztacala, Tlalnepantla, Edo. de México, 54000 México (e-mail: lemos@servidor.unam.mx); and **DAVID CHISZAR**, Department of Psychology, University of Colorado, Boulder, Colorado 80309-0345, USA (e-mail: chiszar@clipr.colorado.edu).

HYLA ACREANA (NCN). **LARVAL BEHAVIOR**. Carnivory in larval anurans is well documented, with the families Hylidae, Leptodactylidae, Myobatrachidae, Pelobatidae, Pipidae, Dendrobatidae, and Ranidae containing species known to have predaceous larvae (McDiarmid and Altig 1999. Tadpoles: The Biology of Anuran Larvae. University of Chicago Press, Chicago

and London. 444 pp.). The role of carnivorous species in tadpole assemblages, however, is poorly known.

During October 2002, I observed *Hyla acreana* tadpoles in the floodplain of the Madre de Dios River in southeastern Peru. *Hyla acreana* adults were most commonly found calling from secondary growth habitat bordering small pools and large puddles. These pools were common breeding habitat for upwards of thirty anuran species (McKeon and Baggallay, in prep.), though dominated by *Phrynohyas venulosus*, *Hamptophryne boliviana*, *Scinax rubra*, and *Hyla leucophyllata*. Tadpoles were captured and reared through metamorphosis for positive identification. Throughout the month, behavioral notes were taken on tadpoles *in situ*, using a mask and snorkel while lying on a balsa raft.

Four instances of depredation by tadpoles of *H. acreana* were recorded. Three prey individuals were larval *Hamptophryne boliviana*, the fourth was a tadpole of an unidentified *Scinax*. Tadpoles of *H. acreana* tended to hover near horizontal structures of submerged vegetation. Upon encountering another tadpole *H. acreana* would dart forward and seize the proximal portion of the prey in its mouthparts. Prey tadpoles were slowly consumed by tearing through the body wall.

Captive specimens of larval *H. acreana* (Gosner stages 28–36) were offered prey types belonging to the following species: *Hyla leucophyllata, Hamptophryne boliviana*, *Phyllomedusa camba*, *Phyllomedusa palliata*, *Scinax rubra*, *Allobates femoralis*, and *Phyrnohyas venulosus.* All were smaller than, or equal in length to the *H. acreana*. All prey species were avidly consumed except for *P. venuslosus*, the most common tadpole found in the pond assemblage.

I thank the Yine Project, Madre de Dios Explorations, and Pantiacolla Tours for their continuing support of herpetological research in the area.

Submitted by **C. SEABIRD McKEON**, Smithsonian Environmental Research Center, P.O. Box 28, 647 Contees Wharf Road, Edgewater, Maryland, USA.

HYLA ALVARENGAI (NCN). **PREDATION**. Amphibians are common prey for a variety of predators (Castanho 1996. Herpetol. Rev. 27:141; Haddad and Bastos 1997. Amphibia-Reptilia. 18:295–298) *Hyla alvarengai* is endemic to the Serra do Espinhaço in the Brazilian states of Minas Gerais and Bahia (Frost 2004. Amphibian Species of the World: an Online Reference. Version 3.0. 22 Aug 2004. Electronic Database accessible at http://research.amnh.org/herpetology/amphibia/index.html). It is a saxicolous hylid, with a relatively large body size (Duellman 1993. Amphibians of the world: additions and corrections. Univ. Kansas Mus. Nat. Hist. Spec. Publ. 21:1–372) and little is known about its biology (see Sazima and Bokermann 1977. Rev. Bras. Biol. 37:413–417; Vrcibradic and Van Sluys 2000. Herpetol. Rev. 31:40–41; Carneiro et al. 2003. Anais de trabalhos completos. V Congresso de Ecologia do Brasil. pp. 563–564).

On 18 Sept 2003 at Serra do Cipó (19º20'S; 43º40'W), Minas Gerais, Brazil, ca. 1200 h, we observed an individual *H. alvarengai* being eaten by a Yellow-headed Caracara at the edge of the MG-010 road. We initially saw the hawk perched on a wall at the roadside while eating an individual *H. alvarengai*. The hawk flew away as we approached, leaving behind only the left tibia (25.9 mm) of a young *H. alvarengai*. The young of *H. alvarengai* preferentially use stones as diurnal resting sites at Serra do Cipó (Carneiro 2003, *op. cit*.), a kind of substrate in which individuals of this species are cryptic (Sazima and Bokermann 1977, *op. cit*.). Nonetheless, the use of an uncovered microhabitat to rest might make young of this species potential prey for visually-oriented predators.

We are grateful to Tadeu J. Guerra for logistical support. This work was completed while CABG received a graduate fellowship from Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES).

Submitted by **LEONARDO L. MACHADO** (e-mail: leolmachado@pop.com.br) and **CONRADO A. B. GALDINO** (e-mail: galdinoc@terra.com.br), Setor de Ecologia, Instituto de Biologia Roberto Alcântara Gomes, Universidade do Estado do Rio de Janeiro. Rua São Francisco Xavier, 524, Maracanã, 20550-013, Rio de Janeiro, Brazil.

HYLA ARILDAE (Teresópolis Treefrog). **DEATH FEIGNING.** Death feigning behavior has been recorded in some neotropical hylid frogs (Azevedo-Ramos 1995. Rev. Brasil. Biol. 55:45–47; Napoli 2000. Herpetol. Rev. 32:36–37; Vrcibradic and Van Sluys 2000. Herpetol. Rev. 31:40–41). *Hyla arildae* is known to occur in forest fragments of the Serra do Mar and Serra da Mantiqueira in southeastern Brazil (Heyer et al. 1990. Arq. Zool., São Paulo, 31:255–256). During March 2004 at 1200 h, at the Parque Municipal das Mangabeiras (19º55'S; 43º56'W; 850 m elev.), Belo Horizonte, Minas Gerais State, we found an adult *Hyla arildae* (47 mm SVL) resting about 1 m above ground on a leaf of a shrub. When we touched the shrub, the treefrog jumped to the ground about 50 cm from its original position. One of us (PCFC) captured the frog by hand, and just after opening the hand we discovered the treefrog was feigning death. Immediately after being captured, the treefrog thrust its forelimbs upwards and remained motionless with eyelids half closed and its hindlimbs sheltered close to the body. We then turned the treefrog belly up, it remained in the same position for about 10 seconds. After that, we put the treefrog on the ground to take photos. It remained motionless for about five seconds then jumped into its surroundings. This is the first record of death feigning in *Hyla arildae*. We thank D. Vrcibradic and M. Van Sluys for suggested revisions to the text and FAPERJ for a grant to PCFC and CNPq for research grants to CFDR.

HYLA CHRYSOSCELIS (Gray Treefrog). **DEPRIVATION TOLERANCE.** On 23 July 2004, a healthy adult *Hyla chrysoscelis* was found inside a sealed 2-cubic-foot bag of red cedar bedding chips by Joann Listwak of North Branch, Lapeer County, Michigan, USA. The treefrog was donated to the Detroit Zoo (accession 11322). According to a representative of the manufacturer the logs for this batch of chips came from Kentucky and/or Alabama and

were shipped to a processing plant in Lebanon, Marion County, Kentucky. Because of the destructive nature of processing (chipping, kiln drying), the frog must have gotten in the bag late in the processing and more likely came from the region of the processing plant than the log source. Because *H. versicolor* is known from just a few counties around Ft. Knox in Kentucky and *H. chrysoscelis* occurs statewide (MacGregor et al. 2004. Frogs and Toads of Kentucky. Available online at www.bioweb.wku.edu/froglogger), I assume this animal is the latter species. The bag was purchased at the Tractor Supply Company store in Lapeer, Michigan between 7–16 July. According to the manufacturer, it takes about 1 month for the bag to go from the manufacturer to the distributor; summertime shipments to the distributor are monthly and all stock is sold within the month, so the bag was likely sealed at the processing plant 30–60 days prior to sale. With an additional 1–2 weeks at the home of the purchaser, this animal was apparently isolated for 5–10 weeks. Unlike in a similar event involving an *Eleutherodactylus planirostris* sealed in a bag of moist mulch for 8 months (Zippel et al. 2005. Herpetol. Rev. 36:299–300), cedar chips are kiln-dried and bagged shortly thereafter so the presence of food and water is unlikely.

Unintentional anthropogenic dispersal of amphibians and other wildlife has become increasingly common as various means of transportation become faster and wider reaching (e.g., Kaiser 1997. Biodiv. Conserv. 6:1391–1407). We regularly receive phone calls at the zoo to identify animals that emerge from plant and produce shipments. This example, in addition to one previously documented (Zippel et al., *op. cit.*), demonstrates how ectotherms are in some ways more likely to be inadvertently dispersed by human activities. Although ectotherms are affected by deprivation (e.g., Audo et al. 1995. Oecologia 103:518–522; Dunlap 1995. J. Herpetol. 29:345–351), their small size and low metabolic needs relative to endotherms (Pough 1980. Amer. Nat. 115:92–112) make them more likely to survive transportation under extreme conditions of deprivation.

Submitted by **KEVIN C. ZIPPEL**, National Amphibian Conservation Center, Detroit Zoo, Royal Oak, Michigan 48068, USA.

HYLA PULCHELLA CORDOBAE (Cordoba Treefrog). **PARASITISM**. Parasitism by copepods on anuran tadpoles is rarely documented. However, such parasitism has been reported on field caught (Baldauf 1961. J. Parasitol. 47[2]:195) and laboratory-reared (Martins and Souza 1996. Rev. Bras. Biol. 12[3]:619–625) *Rana catesbeiana*, and on field caught *R. chalconota* (Tzi Ming 2001. Froglog 46[3]:3).

During February 2002, one of us (LA) collected 46 *Hyla pulchella cordobae* tadpoles (Gosner stages 26–35), from a lotic environment (Arroyo Tanti, Tanti City, Córdoba province, Argentina). Tadpoles were preserved and transferred to the laboratory where we found 9 of them with a total of 12 parasitic copepods (Lernaeidae, *Lernaea* sp.). We observed a maximum of 4 copepods on any one tadpole, whereas the maximum number previously reported varied from 6 (Baldauf, *op. cit.*) to 15 (Tzi Ming, *op. cit.*). All copepods observed by us were anchored at the junction of the body and tail. The damage by parasitic copepods seems to be variable. Tzi Ming (*op. cit.*) observed a 5.5% incidence of external limb abnormalities, although no abnormalities were reported by Baldauf (*op. cit.*), Martins and Souza (*op. cit.*) or us. Tzi Ming (*op. cit.*) found the copepod *L. cyprinacea* on *R. chalconota* tadpoles and fishes of the genus *Poecilia*. Similarly, we observed copepods (*Lernaea* sp.) on *Hyla pulchella cordobae* tadpoles and the fish *Astyanax* sp. and *Jenynsia* sp., which were collected sympatrically.

This information suggests that natural infestations of copepods on anuran tadpoles might occur at both lentic (Tzi Ming, *op. cit.*) and lotic environments. The material examined was deposited at the Invertebrates Collection of the Museo de La Plata (MLP COPEPOD 24). This is Scientific Contribution No. 763.

As., Argentina (e-mail: alcalde@ilpla.edu.ar); and **PATRICIA BATISTONI**, División Zoología de Vertebrados, Sección Ictiología, Museo de La Plata, Paseo del Bosque s/n, 1900, La Plata, Bs. As., Argentina.

HYLA VERSICOLOR (Gray Treefrog). **RECORD SIZE**. Conant and Collins (1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. 3rd Ed. Expanded. Houghton Mifflin, Boston, Massachusetts. 616 pp.) reported maximum size for *Hyla versicolor* as 60 mm SVL. Herein I report a female *H. versicolor* 62.4 mm as determined by standard anuran SVL measurement techniques (Conant and Collins 1998, *op. cit.*) using a vernier caliper. This specimen was collected at the Thomas Baskett Wildlife Research Area 6.7 km E of Ashland, Boone County, Missouri, USA on 15 June 2004. Length and species identification (based on collection location) was confirmed by Richard Daniel. The specimen is deposited in the University of Missouri, Columbia Herpetological Collection (UMC 7709).

Submitted by **JARRETT R. JOHNSON**, 212 Tucker Hall, Division of Biological Sciences, University of Missouri, Columbia, Missouri 65211, USA.

LEPTODACTYLUS LABYRINTHICUS (South American Pepper Frog). **PREDATION**. *Leptodactylus labyrinthicus* lays its eggs in foam nests in basins at margins of water bodies and has aquatic tadpoles (Cei 1980. Monit. Zool. Ital. [NS] Monogr. 2: XII. 609 pp; Silva et al. *in press*. J. Nat. Hist.). The morphology of these tadpoles has been described (Heyer 1979. Smithson. Contr. Zool. 301:1–43; Cei 1980, *op.cit.*), although ecological data are scarce. Here we report field observations of predation upon tadpoles. We observed predatory events in a cement pool (3 m; 10 cm deep), in a garden at the Cerrado Reservation of Parque Estadual de Caldas Novas (17°43'S, 48°40'W), in the municipality of Caldas Novas, Goiás State, Brazil. Observations were made during the day and night in September 2003. During the day (0700–1800 h) we observed the Leaf-scrapper (*Turdus amaurochalinos*) disturbing the dead leaves on the bottom of the pool with its beak and capturing tadpoles. The bird had a nest with two nestlings about 20 m from the pool, and used the captured tadpoles to feed them. The tadpoles were swallowed or carried in the beak. At ca. 1830 h we also observed the snake *Liophis poecilogyrus* (voucher photo: AAG-

UFU 3227) preying on these tadpoles. This snake was captured (ca. 10 min after being found) and it regurgitated 11 tadpoles (38.5 ± 2.4 mm TL), five were still alive.

Predation has been considered the main cause of tadpole mortality (McDiarmid and Altig 1999. Tadpoles: The Biology of Anuran Larvae. University of Chicago Press, 444 pp.). The Leaf-scrapper is an especially efficient diurnal predator because they can dislodge tadpoles from their retreats by removing leaves from the bottom of the pool.

We thank Celine de Melo for identification of the bird and A. A. Giaretta for critically reading the manuscript and identifying the snake.

Submitted by **KENI PAULA R. MUNIZ** (e-mail: keniribeiro@hotmail.com.br) and **WAGNER RODRIGUES SILVA** (e-mail: wagnerdrigues@yahoo.com.br), Laboratório de Ecologia e Sistemática de Anuros Neotropicais, Instituto de Biologia, Universidade Federal de Uberlândia, CEP 38400-902, Uberlândia, Minas Gerais, Brazil.

LEPTODACTYLUS LABYRINTHICUS (South American Pepper Frog). **NECROPHAGY**. On 26 Sept 2003 at a Cerrado reservation in Caldas Novas Municipality (17°43'S, 48°40'W), Goiás State, Brazil, we observed tadpoles of *L. labyrinthicus* gathered around the carcass of a bird (*Turdus* sp.) in a cement pool (ca. 10 cm deep). Observations occurred from 0700–2000 h. We found about 30 tadpoles entering amidst the feathers and biting the carcass. Tadpoles of *L. labyrinthicus* have been reported to feed on tadpoles and frog eggs (Cardoso and Sazima 1977. Ciência e Cultura 29:1130–1132; Silva et al. *in press*. J. Nat. Hist.), but necrophagy was previously unknown. Eggs and carrion may represent a valuable protein source for these tadpoles, and compared to other frogs, animal matter may allow a faster development (McDiarmid and Altig 1999. Tadpoles: The Biology of Anuran Larvae. University of Chicago Press, 444 pp.).

We thank A. A. Giaretta for critically reading this manuscript.

MUNIZ** (e-mail: keniribeiro@hotmail.com.br), Laboratório de Ecologia e Sistemática de Anuros Neotropicais, Instituto de Biologia, Universidade Federal de Uberlândia, CEP 38400-902, Uberlândia, Minas Gerais, Brazil.

LEPTODACTYLUS OCELLATUS (Rã-Manteiga). **CANNIBALISM.** In some animals (Machado and Oliveira 1998. J. Zool. London 246:359–367), including frogs (Townsend et al. 1984. Anim. Behav. 32:421–431), cannibalism is a major factor of mortality of immature individuals. On 6 Aug 2003 in Unaí municipality, Minas Gerais state, Brazil, we collected an adult *Leptodactylus ocellatus* (62.4 mm SVL) and found a cospecific juvenile (30 mm SVL) in its stomach. *Leptodactylus ocellatus* has a broad diet, often feeding on other frogs (Gallardo 1964. Physis – Tomo XXIV N 68:373–384), including conspecifics (present note).

Specimens examined (AAG-UFU 2482, 2494) are housed in Museu de Biodiversidade do Cerrado, in the Universidade Federal de Uberlândia, Minas Gerais state, Brazil. We thank Ariovaldo A. Giaretta for critically reading the manuscript and the owners of the Fazenda Sagres S. A. for logistic support.

MICROHYLA HEYMONSI (Dark-sided Chorus Frog). **ENDOPARASITES.** *Microhyla heymonsi* is known from south-east Asia (Ziegler 2002. Die Amphibien und Reptilien eines Tieflandfeuchtwald-Schutzgebietes in Vietnam. Natur end Tier - Verlag GmbH, Munster, Germany, 242 pp.). To our knowledge there are no reports of endoparasites from this species. The purpose of this note is to report the nematode *Cosmocercoides multipapillata* from *M. heymonsi*.

Two *M. heymonsi* (SVL 21 mm ± 1 SD, range: 20–22 mm) were collected 21 April 1999 from Ha Tinh Province, Huong Son District, (18°20'N, 105°14'E), Vietnam and deposited in the herpetology collection of the Natural History Museum of Los Angeles County, Los Angeles, California as LACM 14682, 14683. The esophagus, stomach, small intestine, large intestine, lungs, and urinary bladder were opened and examined separately for helminths using a dissecting microscope. The body cavity was also searched. One frog (LACM 14683) was found to harbor 5 (2 males, 3 females) nematodes in the large intestine. The nematodes were cleared in a drop of concentrated glycerol, identified as *Cosmocercoides multipapillata* and deposited in the United States National Parasite Collection, Beltsville, Maryland as USNPC 94915. Prevalence of infection (number infected frogs/number frogs examined) × 100 was 50%.

Cosmocercoides multipapillata was described from *Bufo melanostictus* from India (Khera 1958. Ind. J. Helminthol. 10:6–12). It has also been reported in *Bufo gargarizans* from China (Wang 1980. Acta Zootax. Sinica 6:365–372). *Microhyla heymonsi* represents the third host for *Cosmocercoides multipapillata*. Vietnam is a new locality record.

We thank Amanda Woolsey (Whittier College) for assistance with dissections.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb@psu.edu).

PLEURODEMA BUFONINUM (NCN). **DIET**. *Pleurodema bufoninum* is a leptodactylid frog adapted to living under challenging climatic conditions of the Patagonian steppe, at the southern tip of South America (Cei 1980. Amphibians of Argentina. Monit. zool. ital. [N.S.], Monogr. 2:1–609). The species is widely distributed in the Argentine Patagonia, but in Chile it is restricted to the few steppe areas that exist west of the Andes. Little is known about its biology, with the only reference to its diet from nine specimens collected in Chile, between Pino Hachado and Icalma. Both

areas are on the frontier with Argentina (38º40'–38°50'S; 71ºW; 1200–1800 m elev.) (Pincheira-Donoso 2002. Gayana 66[1]:77–80). Nothing is known about the species' feeding ecology in the Argentine Patagonia. This note describes for the first time the diet of *P. bufoninum* collected east of the Andes.

On 9 March 2004 (late summer), during hot weather conditions (29°C), at 1530 h, we found *P. bufoninum* juveniles active, sheltering in the shade of a bridge on the shore of the Pichileufú River (Paso Flores, Río Negro Province, Argentina, 40°36'S, 70°39'W; 575 m elev), 3–5 m away from the water. The general surroundings are typical of the Patagonian steppe (semi-desert with xerophytic, stunted bushes less than 0.6 m tall alternating with grasses). On this occasion, the frogs were found at the highest, driest sites of the alluvial terrain, where there are only cobbles and boulders. Immediately after being captured, the frogs were killed and fixed in 10% formalin for later analysis. We examined 5 newly metamorphosed specimens (Gosner stages 45 and 46); measuring between 19.9 and 23.5 mm TL (mean 22.1 ± 1.57 mm). We identified stomach contents to family or order level. We recorded the number of items of each prey taxon and calculated its frequency of occurrence. We estimated the rate of feeding activity as the percentage of stomachs containing food with respect to the total number of stomachs examined (Sala and Ballesteros 1997. Mar. Ecol. Prog. Ser. 152:273–283). The percentage of stomachs containing food was 100%. We found 2–10 prey items per stomach. All prey were arthropods, and there was no plant material in the stomachs. Numerically, the diet was made up of hymenopterans (48%), coleopterans (44%), and Araneae (8%). In particular, ants (Formicidae) were the most abundant prey item (40%), followed by Hydrophilidae larvae (24%) and adult Carabidae and Curculionidae (20%). Non-Formicidae hymenopterans and Araneae were consumed in equal proportions (8%). The most frequently occurring items were Formicidae (100%), Hydrophilidae larvae (60%), and Araneae (40%).

Comparison of our results with Pincheira-Donoso (2002, *op. cit.*) shows that in both cases ants were the most abundant item in the diet of *P. bufoninum.* Coleopterans were more numerous and more frequent in our study, and they add two new families to known prey items (Curculionidae and Hydrophilidae). Hemiptera, Diptera, Homoptera, Acari, and Gastropoda, and seeds and plant remains were not present in our sample. Thus, based on our results, *P. bufoninum* feeds on a smaller number of prey taxa.

Our results complement the only previous data available on the diet of this species, and provide information on the trophic behavior of newly metamorphosed juveniles, at a lower altitude east of the Andes. Our results support the idea that the species is opportunistic, adapts to local conditions, and includes terrestrial walking and flying arthropods and aquatic coleopteran larvae in its diet.

Submitted by **MARÍA T. BELLO** (e-mail: bellomaria@bariloche.com.ar), **VIRGINIA HOUGHAM, CARMEN A. ÚBEDA**, and **MARIA E. CUELLO,** Centro Regional Bariloche, Universidad Nacional del Comahue, Unidad Postal Universidad, R 8400 FRF Bariloche, Provincia de Río Negro, Argentina.

POLYPEDATES LEUCOMYSTAX (Java Whipping Frog). **ENDOPARASITES.** *Polypedates leucomystax* is known from India, southeast Asia, and Japan (Ziegler 2002. Die Amphibian und Reptilien eines Tieflandfeuchtwald-Schutzgebietes in Vietnam. Natur end Tier - Verlag GmbH, Munster, Germany, 342 pp.). To our knowledge, there are no reports of helminths from *P. leucomystax* collected in Vietnam. The purpose of this note is to report the nematode *Cosmocercoides mutltipapillata* and the acanthocephalan *Acanthocephalus bufonis* in *P. leucomystax.*

Two *P. leucomystax* (SVL 57 mm ± 4 SD, range = 54–59 mm) were collected 17 April 1999 from Ha Tinh Province, Huong Son District, (18°20'N, 105°14'E), Vietnam and deposited in the herpetology collection of the Natural History Museum of Los Angeles County, Los Angeles, California as 146820 and 146821. The esophagus, stomach, small intestine, large intestine, lungs, and urinary bladder were opened and examined separately for helminths using a dissecting microscope. The body cavity was also searched. Helminths were cleared in a drop of concentrated glycerol. One frog (LACM 146820) was found to harbor 6 (5 males, 1 female) *Cosmocercoides multipapillata* and 3 (2 males, 1 female) *Acanthocephalus bufonis,* both in the small intestines. Helminths were deposited in the United States National Parasite Collection (USNPC) as *Cosmocercoides multipapillata* (94916) and *Acanthocephalus bufonis* (94917). Prevalence of infection (number infected frogs/number frogs examined) ×100 was 50% for each helminth.

Cosmocercoides multipapillata was originally described from *Bufo melanostictus* from India (Khera 1958. Ind. J. Helminthol. 10:6–12). It has also been reported in *Bufo gargarizans* from China (Wang 1980. Acta Zootax. Sinica 6:365–372). *Acanthocephalus bufonis* has an Oriental distribution where it is known from bufonids, ranids, and the lacertid lizard *Takydromus sexlineatus* (Kennedy 1982. Can. J. Zool. 60:356–360). It also occurs in *Bufo marinus* in Hawaii (Barton and Pichelin 1999. Parasite 6:269–272). *Cosmocercoides multipapillata* represents a new helminth species record for *P. leucomystax*. Vietnam is a new locality record for *C. multipapillata* and *A. bufonis*.

We thank Amanda Woolsey (Whittier College) for assistance with dissections.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb@psu.edu).

PSEUDACRIS CADAVERINA (California Treefrog). **PREDATION.** During an electro-shocking survey on 12 August 2004 (1145 h), a juvenile Largemouth Bass (*Micropterus salmoides*; 120 mm TL) was collected from a small pool (ca. 10 m × 1.5 m, 40 cm) from San Mateo Creek, San Diego County, California, USA (T8S, R6W, Sec 24). Upon capture it was noticed that the rear legs of an adult *P. cadaverina* were protruding from the mouth of the *M. salmoides*. The frog had been partially digested when discovered and an examination of the legs of the *P. cadaverina* showed no abnormalities or decay leading us to conclude that the frog had been consumed live.

To our knowledge, this is the first documentation of predation of *P. cadaverina* by *M. salmoides*. Previously documented nonnative fish predators on *P. cadaverinia* include Rainbow Trout,

Oncorhynchus mykiss (hatchery raised-stock variety) and Green Sunfish, *Lepomis cyanellus* (Ervin 2005. *In* M. Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 467–470. Univ. California Press, Berkeley and Los Angeles).

At the site of collection *M. salmoides* is an introduced invasive predatory fish. *Micropterus salmoides* has been widely introduced in North America (Courtenay and Stauffer 1984. Distribution, Biology, and Management of Exotic Fishes. John Hopkins University, Baltimore, Maryland) and has been implicated as a contributing factor in the declines of native amphibian populations (Hayes and Jennings 1986. J. Herpetol. 20:490–509; Fisher and Shaffer 1996. Cons. Biol. 10[5]:1387–1397).

The *M. salmoides* with the partially digested *P. cadaverina* remains, protruding from its mouth, were preserved in formalin and deposited, along with two digital prints of the specimen, in the Herpetological Collection at the California Academy of Sciences as vouchers (CAS 228883).

Submitted by **TIM E. HOVEY**, California Department of Fish and Game, 4949 Viewridge Avenue, San Diego, California 92123, USA (e-mail: thovey@dfg.ca.gov); and **EDWARD L. ERVIN**, Merkel and Associates, Inc., 5434 Ruffin Road, San Diego, California 92123, USA (e-mail: EErvin@merkelinc.com).

PSEUDACRIS CRUCIFER (Spring Peeper). **PREDATION**. Because *Pseudacris crucifer* larvae are palatable (Kats et al. 1998. Ecology 69:1865–1870), they are typically excluded from wetlands containing predatory fishes (Hecnar and M'Closkey 1997. Biol. Cons. 79:123–131). Whether the allotopic distribution of *P. crucifer* and predatory fishes is the result of predation by fishes on *P. crucifer* eggs, larvae, or adults, or is the result of avoidance behavior by adult *P. crucifer* is unknown.

On 3 Feb 2004, I removed a Redfin Pickerel (*Esox americanus*; 13 cm TL) from a minnow trap set in a 0.2-ha isolated wetland on Moody Air Force Base, Lanier County, Georgia USA. A distended gut indicated that the fish had recently eaten. Upon dissection, I removed an adult male *P. crucifer* from the fish. Additional adult *P. crucifer* were captured in minnow traps and in funnel traps set at a drift fence adjacent to the wetland. The capture of amplexed pairs and spent females indicated breeding by *P. crucifer* despite the presence of a suite of predatory fishes (*Centrarchus macropterus*, *Elassoma evergladei*, and *Gambusia holbrooki*, in addition to *Esox*). Dipnetting and minnow trapping in March did not yield any *P. crucifer* larvae, suggesting complete reproductive failure.

The exclusion of certain species of amphibians from wetlands inhabited by predatory fishes has been explained as the result of predation (Knapp et al. 2001. Ecol. Monogr. 71:401–421) or adult avoidance (Hopey and Petranka 1994. Copeia 1994:1023–1025; Binckley and Resetarits 2003. Oikos 102:623–629). My observation of *P. crucifer* breeding with, and being preyed upon by, *E. americanus* suggests *P. crucifer* is excluded from wetlands inhabited by predatory fishes by predation and not by adult avoidance behavior.

Surveys at Moody AFB are supported by the United States Air Force through a contract administered by the Center for Reptile and Amphibian Conservation and Management, Fort Wayne, Indiana, and are authorized by Georgia scientific collection permit 29-WMB-04-147.

RANA CATESBEIANA (American Bullfrog). **CHYTRIDIOMYCOSIS**. Infection by the chytrid fungus *Batrachochytrium dendrobatidis* has been associated with mass mortality of anuran amphibians in Europe, Latin America, Australia, and North America (Berger et al. 1998. Proc. Nat. Acad. Sci. USA 95:9031–9036; Bosch et al. 2001. Biol. Cons. 97:331–337; Green et al. 2002. Ann. New York Acad. Sci. 969:323–339). As of May 2004, chytridiomycosis has been confirmed in at least 69 species of anurans worldwide (Berger et al. 1999. *In* Campbell [ed.], Declines and Disappearances of Australian Frogs, pp. 23–33. Environment Australia, Canberra; Green et al., *op. cit.*; Speare and Berger. Global distribution of chytridiomycosis in amphibians. http://www.jcu.edu.au/school/phtm/PHTM/frogs/chyglob.htm, 19 March 2004).

Chytridiomycosis has recently been found in native larval and post-metamorphic American Bullfrogs (*Rana catesbeiana*) in southeastern North America (Green et al., *op. cit.*), and in introduced larval bullfrogs in Uruguay, South America (Mazzoni et al. 2003. Emerging Infectious Diseases 9:995–998) and California, USA (G. Fellers and D. Green, unpubl. data). Here, we report chytridiomycosis in an adult bullfrog in western Oregon, USA. To our knowledge, this is the first reported case of chytridiomycosis in a free-living amphibian west of the Cascade Range in the Pacific Northwest.

On 08 Feb 2004, we captured an adult male bullfrog (99 mm SVL, 62 g), near Fern Ridge Reservoir in the southern Willamette Valley (UTM 0472617E, 4878466N; 117 m elev.). The bullfrog had atypical diffuse reddening of the ventral skin. The bullfrog was held alone in a laboratory aquarium for 8 days and was offered live crickets. The bullfrog became increasingly lethargic and was found dead on the ninth day of captivity. It was promptly frozen and mailed to the USGS National Wildlife Health Center for examination. Histological examinations of the ventral skin and toewebs showed mild to moderate numbers of chytrid thalli within keratinized epithelial cells only. Autolysis and freeze artifacts caused sloughing of much epidermis, hence the distribution and intensity of the host response may have been greater than what was detected histologically.

Our observation confirms the presence of *B. dendrobatidis* in the Willamette Valley, Oregon. Several factors suggest that bullfrogs could pose a threat to native amphibians by serving as disease reservoirs or vectors for *B. dendrobatidis* (see Daszak et al. 2003. Diversity and Distributions 9:141–150). Bullfrogs are introduced into at least four continents and are widespread in the lowlands of western North America (Bury and Whelan 1984. USDI Res. Publ. 155. Washington, DC. 23 pp.). Bullfrog farming operations are expanding in Latin America, and trade in bullfrogs is global (Mazzoni et al., *op. cit.*). Most bullfrog larvae overwinter in the Pacific Northwest (Bury and Whelan, *op. cit*.; Nussbaum et al. 1983. Amphibians and Reptiles of the Pacific Northwest. Univ. Idaho Press, Moscow. 332 pp.). Multiple species of overwintering ranid larvae (including *R. catesbeiana*) are known to develop oral

chytridiomycosis (Fellers et al. 2001. Copeia 2001:945–953; Mazzoni et al., *op. cit.*). A protracted larval stage may increase exposure to *B. dendrobatidis* and increase the likelihood of infection compared to single-season larvae (Fellers et al., *op. cit.;* Bosch et al., *op. cit*.). Mortalities among anuran larvae with oral chytridiomycosis have not been reported (Fellers et al., *op. cit.*). However, long-lived larval bullfrogs may serve as year-round reservoirs of *B. dendrobatidis,* and following completion of metamorphosis, may become vectors of the infection without demonstrating clinical signs or exceptional mortality rates (Daszak et al., *op. cit.*; Mazzoni et al., *op. cit.*). Moreover, laboratory experiments using fungal isolates suggest that transmission of *B. dendrobatidis* can occur between congeneric anurans, as well as between urodeles and anurans (Davidson et al. 2003. Copeia 2003:601–607; Nichols et al. 2001. J. Wildl. Dis. 37:1–11). Disease transmission is of particular concern in the Pacific Northwest, where bullfrogs occur sympatrically with native ranid species of concern (e.g., *Rana pretiosa, R. aurora, R. boylii*). We encourage further study of *Batrachochytrium* infection in Bullfrogs in western North America, and reiterate the need for researchers to wash and disinfect field gear between field sites.

The specimen is deposited in the National Wildlife Health Center Archives, #18972. This work was supported by the U.S. Department of Interior, Amphibian Research and Monitoring Initiative. We thank R. B. Bury and R. L. Hoffman for review and the U.S. Army Corps of Engineers for access to the study site. This animal was collected under a Scientific Collecting permit from the Oregon Department of Fish and Wildlife.

RANA CATESBEIANA (American Bullfrog). **DIET**. Predation on vertebrates by adult American Bullfrogs is well documented (Bury and Whelan 1984. US Fish and Wildlife Serv. Publ. 155. USDI, Washington, DC). A recent literature review of prey items listed eight species of snakes taken as prey (Casper and Hendricks 2005. *In* Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 540–546. Univ. California Press, Berkeley), including one species of rattlesnake, *Crotalus atrox* (Clarkson and DeVos 1986 J. Herpetol. 20:42–49) Herein I report another rattlesnake species (*C. oreganus*) previously undocumented as American Bullfrog prey.

On the evening of 17 May 2004, I collected a male (160 mm SVL, 384 g) and female (160 SVL, 503 g) *R. catesbeiana*, in amplexus, in End-of-the-Line Pond in Santa Clara County, California, USA (37º23'15.042"N, 121º44'51.413"W). The frogs were humanely killed and placed on ice overnight. They were subsequently dissected for stomach content analysis. The stomach of the gravid female contained a nearly intact *C. oreganus* (SVL not available; remaining carcass was 260 mm in length and weighed 12.5 g). This is the second documented case of *R. catesbeiana* eating rattlesnakes with no apparent ill effects.

I thank Mark R. Jennings for advice on processing specimens. Specimens were obtained under California fishing license number 044275-20. The frog and its stomach contents have been accessioned into the permanent collection at the Museum of Vertebrate Zoology, University of California, Berkeley (Accession No. MVZ 13907).

RANA CHIRICAHUENSIS (Chiricahua Leopard Frog). **REPRODUCTION**. Northern populations of *Rana chiricahuensis* occur along the southern edge of the Colorado Plateau in central and eastern Arizona and western New Mexico in the USA, while southern populations are found in southeastern Arizona, southwestern New Mexico, and in northern Sonora, the Sierra Madre Occidental of Chihuahua, and northern Durango in Mexico (Platz and Mecham 1979. Copeia 1979:383–390). This species is federally listed as threatened in the USA (U.S. Fish and Wildlife Service 2002. Fed. Regist. 67:40790–40811, 13 June 2002), thus additional life history information is important to aid recovery efforts. Winter breeding of northern populations of *R. chiricahuensis* at high elevation sites in Arizona has not been reported previously. Populations of *R. chiricahuensis* inhabiting sites above 1800 m elev. in Arizona and New Mexico were thought to have a short breeding season that spanned June through August (Frost and Platz 1983. Evolution 37:66–78). Data from New Mexico, including observations of egg masses in December and March and young tadpoles in December, January, February, and March, indicate that winter breeding above 1800 m is possible in areas fed by warm springs of 21–28°C (Jennings 1988. Ecological Studies of the Chiricahua Leopard Frog, *Rana chiricahuensis*, in New Mexico. New Mexico Dept. Game and Fish, Santa Fe, New Mexico, 14 pp.; Scott and Jennings 1985. Occas. Pap. Mus. Southwest. Biol. 3:1–21). On 21 Feb 2002 at 1225 h, we discovered two eggs masses in a 0.2 ha spring-fed pond at 2546 m elev. in the Three Forks area of Apache-Sitgreaves National Forest, Apache County, Arizona, USA. Snow still covered the surrounding hillsides and made many forest roads impassible. Thin ice was present along the grassy edges of the pond. The egg masses were 55 cm apart and located on the NE side of the pond. A spring vent, identifiable by a line of gravel and light upwelling of water, ran lengthwise between the two egg masses. The temperature of the water at each egg mass and at the spring vent was 18°C. Water temperature 6 m away from the eggs was 14°C. Air temperature was 15°C. The first egg mass was 8 × 6 × 4 cm and was located 24 cm from the shore in water 5.5 cm deep with the top of the egg mass 1 cm below the water's surface. The second egg mass was 10 × 5 × 4 cm and was 18 cm from the shore in water 6.5 cm deep with the top of the mass at the water's surface. Algae surrounded both egg masses. The embryos of the first and second masses were at Gosner stage 15 and 12. The next day at 1015 h embryos in the first egg mass had reached Gosner stages 16–17 and in the second mass stages 12–14.

On 25 February, we collected a small portion of each egg mass for our captive rearing and release program, which also allowed us to confirm the identity of the resulting metamorphs. The first egg mass had mostly hatched in captivity by 28 February and the

second by 2 March.

We continued to survey for eggs masses that season prior to our normal June start date. In the same area of the pool we found 5 egg masses 2–6 April and 2 masses on 15 May 2002.

Our work was partially funded by the Arizona Game and Fish Department's Heritage Fund, donations to Arizona's Nongame Wildlife Checkoff, and Section 6 funds from the US Fish and Wildlife Service.

RANA PRETIOSA (Oregon Spotted Frog). **PREDATION**. North American river otters (*Lontra canadensis*) consume varying numbers of amphibians, but a high metabolic rate (Iversen 1972. J. Comp. Physiol. 81:341–344; Brown and Lasiewski 1972. Ecology 53:939–943) coupled with most dietary studies being biased toward gut contents and scats (versus direct observations) has often prevented identifying amphibian prey to species (e.g., Field 1970. Michigan Academician 3:49–58; Greer 1955. Amer. Midl. Nat. 54:299–313; Knudsen and Hale 1968. J. Wildl. Mgmt. 32:89–93; Wilson 1954. J. Wildl. Mgmt. 18:199–207). Even among studies in which prey identification was generally thorough, few amphibians were identified to genus or species (e.g., Lagler and Ostenson 1942. J. Wildl. Mgmt. 6:244–254; Ryder 1955. J. Wildl. Mgmt. 19:497–498; Toweill 1974. J. Wildl. Mgmt. 38:107–111). Scarcity of such data led us to report direct observations of *L. canadensis* predation on the Oregon Spotted Frog (*Rana pretiosa*), from south-central Washington, USA.

We made these observations at Conboy Lake National Wildlife Refuge (CLNWR), Klickitat County (45º55–59'N, 121º15–23'W; elev. 550 m) during the course of a study of *R. pretiosa* (1997–2004). The 1970-ha Conboy Lake wetland complex, 70% of which comprises CLNWR, is a seasonally fluctuating marsh fed by three largely channelized creeks and a series of springs. A mosaic of native sedges (*Carex*) and grasses (especially *Glyceria*), as well as introduced reed canarygrass (*Phalaris arundinacea*) dominate this marsh.

At 1306 h on 28 Feb 2000, CBH and MPH detected a group of five otters in Outlet Creek (the channel which drains the Conboy Lake wetland complex). Weather was sunny with a 7ºC air temperature and a 4ºC water temperature in the creek. When first observed, the otters were ca. 150 m east of the Glenwood-BZ Highway bridge. In the area of observation, Outlet Creek was diked, steep-banked, 6 m wide and 3 m deep. Concealing themselves behind the east bridge barrier, CBH and MPH watched through binoculars as the otters slowly swam toward them. The group would periodically stop and dive in what seemed to be a search of the submerged channel bank and bottom. As the otters approached within 10 m, one surfaced with a large (> 80 mm SVL) Oregon spotted frog in its mouth. Based on its large size and the broad extent (i.e., across the chest) of the orange wash, the frog was probably a female (MPH, unpubl. data). After briefly biting the frog's head, the otter swallowed it whole and dove, and the otter group continued its approach. When ca. 5 m from the bridge, one otter saw CBH and MPH, and immediately gave a series of whistles and grunts. Following the vocalizations, the entire otter group reversed direction and rapidly swam away.

At 1205 h on 5 Sept 2000, CJR observed two *R. pretiosa* (ca. 50 and 65 mm SVL) sitting ca. 20 cm from each other in a large pondweed (*Potamogeton natans*) mat that covered much of the water surface of Bird Creek. At this site (200 m E of Glenwood-BZ Highway), Bird Creek was ca. 1.3 m deep with banks grown to reed canarygrass and scrubby willow (*Salix* sp.), and had a 7.7ºC mid-channel (unvegetated) water temperature. At 1220 h, three adult river otters were observed to surface simultaneously < 3 m from the frogs. The otters submerged and surfaced several times over the next minute until one of them surfaced under the larger of the two spotted frogs, capturing it with a quick movement as the frog attempted to escape. The other frog dove beneath the mat. The otter that made the capture shook its head briefly, the anterior portion of the frog (all but the hind legs) protruding from the its mouth, then dove. The other two otters then noticed CJR, hissed, and also dove. All three resurfaced seconds later 20 m further downstream, the captured frog was no longer visible.

Rana pretiosa is only the fourth ranid frog species that has been unequivocally identified as North American river otter prey; the others are the American Bullfrog (*Rana catesbeiana*: Loranger 1981. Proc. Worldwide Furbearer Conf. 1[1]:599–605; Wilson, *op. cit*.), Green Frog (*Rana clamitans*; Ryder, *op. cit*.), and Northern Leopard Frog (*Rana pipiens*; Ryder, *op. cit*.). Oregon Spotted Frogs are highly aquatic (i.e., nearly all breeding, non-breeding active-season, and overwintering activities occur in aquatic habitat; Watson et al. 2003. J. Herpetol. 37:292–300; JDE, MPH, unpubl. data), so significant opportunities exist for the highly aquatic *L. canadensis* (Melquist and Hornocker 1983. Wildl. Monogr. 83:1–60) to prey on *R. pretiosa*. Moreover, drought or late summer conditions may increase vulnerability to otter predation at CLNWR as aquatic habitats largely recede to the channelized creeks and their diversion ditches. Some Oregon Spotted Frogs also overwinter in these structure-limited channels (JDE, MPH, unpubl. data), locations that may make them vulnerable to the river otter's aquatic-edge foraging mode (Melquist and Hornocker, *op. cit*.).

United States Fish and Wildlife Service grants and a conservation grant from Oregon Zoo Foundation supported this research. This work represents a contribution from the Science Division of the Habitat Program of the Washington Department of Fish and Wildlife.

HAYES**, 2636 59th Avenue NW, Olympia, Washington 98502-3449, USA (e-mail: charleens@aol.com); and **JOSEPH D. ENGLER**, Ridgefield National Wildlife Refuge Complex, Ridgefield, Washington 98642-0457, USA (e-mail: joe_engler@fws.gov).

RANA PRETIOSA (Oregon Spotted Frog). **AGGREGATION AND HABITAT USE**. Adult ranid frogs in western North America

generally disperse after spring breeding, and reports of aggregations after breeding season are limited (see Pope and Matthews 2001. Copeia 2001:787–793; Pilliod et al. 2002. Can. J. Zool. 80:1849–1862; Bulger et al. 2003. Biol. Cons. 110:85–95). As our literature search yielded no direct observations of aggregations of Oregon Spotted Frogs (*Rana pretiosa*), we report an early fall aggregation of adult *R. pretiosa* at Penn Lake (UTM 586800 E, 4866800 N; elev. 1445 m) in the Cascade Mountains, Oregon, USA.

At 1500 h on 20 Sept 2002 (air temp. ca. 20°C), we observed an adult *R. pretiosa* in shallow water dive beneath the edge of a large, flat boulder (2m × 1m × 0.4m). We lifted the boulder to find 9 adult male *R. pretiosa* (mean SVL 67.8 mm; range 59–74 mm) between underlying cobbles in water 5–20 cm deep. The boulder was located in a ca. 25 m-wide bay that receives the 2 main inflows in Penn Lake. The boulder was located ca. 5 m from the larger of these two inflows; heavy discharges during late-spring snowmelt keep the substrate around this main inflow clear of sediment and vegetation. The cobble/boulder substrate at this inflow represents < 2% (< 900 m^2) of the surface area of Penn Lake, and contrasts strongly with the organic sediments and heavy emergent vegetation in littoral zones around the rest of the 8.9-hectare lake. This is our first observation of aggregated *R. pretiosa* in >100 person-hours over 7 years of summer surveys at Penn Lake. During surveys at this and other *R. pretiosa* sites in the central Oregon Cascades, we typically find *R. pretiosa* adults occurring singly in or near warm, vegetated, shallows with flocculent substrate, which is used by frogs as escape cover (Licht 1986. Amer. Midl. Nat. 115:239–247).

The late-September timing of this observation, the atypical habitat, and the proximity of this aggregation to features sought by other ranids as overwintering sites (rock crevices, inflow streams, and associated springs) suggest that these Oregon Spotted Frogs were moving toward or were already in an overwintering location. Little is known of the overwintering habits of *R. pretiosa* (Watson et al. 2003. J. Herpetol. 37:292–300).

These observations were made during work funded by the Willamette National Forest and the U.S. Fish and Wildlife Service. We thank C. Friesen and L. Todd for assistance securing research funds and R. L. Hoffman and R. B. Bury for reviews of the manuscript. Animals were handled under a scientific collecting permit from the Oregon Department of Fish and Wildlife.

SCINAX NASICUS (Lesser Snouted Treefrog). **PREDATION**. Birds are important predators on amphibians (Duellmann and Trueb 1994. Biology of Amphibians. Johns Hopkins, Baltimore. 670 pp.). *Scinax nasicus* is a small hylid that occurs in Paraguay, northern Argentina (south to Buenos Aires province), Uruguay, eastern Bolivia, and southern Brazil along the drainages of the Paraná and Paraguai Rivers (Frost 2002. Amphibian Species of the World: An online reference V2.21). On 27 Sep 2003 at ca. 0850 h I found an adult *Scinax nasicus* being preyed upon by a Great Kiskadee (*Pitangus sulphuratus*) along a fence in the Brazilian Pantanal, Nhumirim Ranch (18º59'S, 56º40'W), Mato Grosso do Sul State. The bird held the frog in its beak, and struck the frog on the fence until it was dead. The bird then swallowed the frog and flew away. *Scinax nasicus* sometimes vocalizes during the day, which might expose it to diurnal predators.

SCINAX RUBER (Red Snouted Treefrog). **ARBOREALITY AND PARACHUTING**. Aerial descent in anurans occurs as both gliding and parachuting. Gliding is aerial descent at an angle <45° to the horizontal whereas parachuting is descent at >45° to the horizontal. Parachuting is known in several anurans including *Rhacophorus*, *Agalychnis*, and *Eleutherodactylus coqui* (Emerson and Koehl 1990. Evolution 44:1931–1946; Roberts 1994. J. Herpetol. 28:193–199; Stewart 1985. J. Herpetol. 19:391–401, and references therein), and it is suspected that many arboreal frogs may be capable of parachuting (Stewart 1985, *op. cit.*). Here we report on arboreal activity and parachuting in *Scinax ruber* from Gamboa, Panama.

Males of *S. ruber* call from the ground or low vegetation, and individuals and amplectant pairs can be found in shrubs and small trees. Arboreal activity at greater heights has not been reported although it is suspected (Ibañez et al. 1999. The Amphibians of Barro Colorado Nature Monument, Soberania National Park and Adjacent Areas. Editorial Mizrachi and Pujol, Panama. 192 pp.). Between 8–11 Aug 2004, we observed at least 20 *S. ruber*, including males and females, on the Gamboa Rainforest Resort Canopy Tower at heights up to 25 m, which is the top of the canopy. When approached or subsequent to a gentle touch, individuals jumped from the tower and descended to the ground, nearby vegetation, or to lower portions of the tower. Aerial descent was controlled and at angles >45°, which classifies it as parachuting.

On 8 Aug 2004 between 2200–2300 h, we observed eight *S. ruber* on the canopy tower. We returned the following night between 2325–0030 h (24.8°C at 25 m height) and observed 20 *S. ruber* of which 16 were captured and sexed. Aerial descents of these 16 individuals were observed, and we recorded the height at which each frog was found and the landing height to determine the vertical descent distance and also recorded the landing substrate (Table 1). Seven males, seven females, and two individuals of unknown sex were found. The average height at which individuals were found was 21.26 ± SE 1.01 m and the average vertical distance descended was 15.03 ± 1.63 m. Six of the females were gravid with eggs visible through the skin.

On 10 Aug between 2045–2115 h, ten *S. ruber* were observed on the canopy tower and another individual was observed in the top of a young palm 13.59 m from the ground. On 11 Aug between 1945–2030 h, 6 individuals were observed on the tower. These were weighed; two gravid females weighed 3.75 and 4.8 g while the four males weighed 2.5, 2.75, 3.35, and 4.15 g. Previous individuals observed appeared to be of similar sizes, and all ap-

peared to be adults. Only one non-gravid female was found on the tower throughout the four observations. Although males with vocal sacs were observed in the tower, we did not detect any calling activity. Among all descents observed between 8–11 Aug (N = 44), the maximum horizontal distance covered was ca. 7 m, but most descents resulted in less than 4 m of horizontal travel. Two individuals that originally descending with their heads away from the tower rotated 180° to land lower on the tower. One of these traveled ca. 1 m out from the tower before rotating and returning to the tower. Another frog turned ca. 130° and landed on a palm. Other individuals either turned smaller amounts or did not turn before landing on the ground, tower, or nearby vegetation.

While parachuting, individuals held their arms and legs lateral to the body, bent, and partially extended. Fingers and toes were spread. This is a common posture in frogs capable of aerial descent (Emerson and Koehl, *op. cit.*). Gliding frogs typically have enlarged hands and feet with extensive webbing between digits and accessory skin flaps on the limbs (Emerson and Koehl, *op. cit.*). *Scinax ruber* lack these characters and only have moderately webbed feet with reduced webbing between the first and second toes and only basal webbing on the hands (Ibañez et al. *op. cit.*). Unlike in the parachuting frogs examined by Emerson and Koehl (*op. cit.*), however, *S. ruber* is capable of turning during descent. These observations confirm the suspicions of arboreal activity in *S. ruber* and demonstrate their capabilities for aerial descent via parachuting.

We thank Stan Rand for his support, Jim McGuire for comments on parachuting behavior, Karin Akre and Andrés Vargas for field assistance, and the Gamboa Rainforest Resort for access to the tower. These observations were possible due to the support of a NSF grant (No. 0078150) for studies of *Physalaemus pustulosus* in the same area.

TABLE 1. Sex, height observed, descent distance, and landing substrate of 16 *Scinax ruber*. Asterisks denote gravid females. Individual 5 turned ca. 90° around a corner of the tower, landing among several tree branches before we could accurately observe the landing height.

SPEA HAMMONDII (Western Spadefoot). **REPRODUCTION**. *Spea hammondii* is restricted to semi-arid regions characterized by great variation in the amount, timing, and duration of rainfall, between and among years. Breeding activity of *S. hammondii* is closely associated with rainfall events and the availability of ephemeral pools (Jennings and Hayes 1994. Amphibian and Reptile Species of Special Concern in California. California Dept. Fish Game. Final Report Contract No. 8023. 94 pp.). Breeding has been reported to take place from January through May (Storer 1925. Univ. California Publ. Zool. 27:153–163; Brown 1976. Contrib. Sci. Los Angeles Co. Mus. Nat. Hist. 286:11; Stebbins 2003. Western Reptiles and Amphibians, 3rd. ed. Houghton Mifflin Co., Boston).

On 26 and 28 Dec 1996, SVC and ELE, observed *S. hammondii* larvae (ca. 4–10 mm TL) in an unshaded ephemeral pool that had formed in a road rut (3 m × 1 m, 15 cm deep) on a mesa dominated by a sage scrub/mixed grassland vegetation community at Mission Trails Regional Park, San Diego County, California, USA (32°50'86"N, 117°04'13"W, 248 m elev.).

On 30 Dec 1996, ELE observed *S. hammondii* larvae (ca. 13–15 mm TL) in an unshaded ephemeral pool that had formed in a road rut (5 m × 1 m, 20 cm deep) on a mesa dominated by chamise chaparral, University City, San Diego County (32°52'07"N, 117°11'43"W, 114 m elev.).

On 10 Nov 2002, ELE observed *S. hammondii* egg masses (N = 43) in an unshaded ephemeral pool that formed in a road rut (11 m × 2.5 m, 25 cm deep) surrounded by grassland at Mesa Del Arroz Preserve, Alpine, San Diego County (32°49'260"N, 116°45'076"W, 600 m elev.). An egg mass consisting of 22 egg capsules (Gosner stages 1–3) was collected and deposited in the herpetological collection of the California Academy of Science (CAS 226121).

On 9 Nov 2002, ELE observed *S. hammondii* egg masses (N = 26) in an unshaded vernal pool (3 m × 1 m, 15 cm deep) on the same mesa (as mentioned above) at Mission Trails Regional Park, San Diego County (32°50'159"N, 117°04'269"W, 255 m elev.). An egg mass consisting of 10 egg capsules (Gosner stages 8–9) was collected (CAS 226120). On 21 Nov. 2002, CDS and ELE salvaged 63 larvae from the same pool because the pool was in the final stages of drying (0.3 m diameter, 3 cm deep) as a result of evaporation and lack of additional precipitation (14–16 mm TL, Gosner stage 25) (CAS 226122–123). The pool had dried by 22 Nov. prior to any larvae successfully metamorphosing, resulting in 100% mortality. The pool refilled in late Nov due to rainshowers and on 8 Dec *S. hammondii* larvae (ca. 5–8 mm TL) were observed. During subsequent visits the pool was again drying prior to the metamorphosis of the larvae. On 24 Jan 2003, CDS and ELE found no surface water and clusters of dead *S. hammondii* larvae (~1800) in the wet mud of the pool basin. Approximately 200 of these slightly desiccated larvae were collected (19–33 mm TL, Gosner stages 25–30).

In the same vernal pool described above, CDS and ELE observed *S. hammondii* egg masses (N = 33) on 22 and 24 Oct 2004.

On 24 Oct the embryos within the majority of egg clusters were motile indicating that they were in the final stages of development prior to emergence from their egg capsules. Using back calculation, the spawn was determined to be six days old, based on the stage of development and the rate of development, with the approximate daytime high for the last six days at ca. 24°C. It was determined that breeding occurred on 17–18 Oct, in response to the first measurable rainfall received in this region in 181 days (April–Oct 2004). This extended period of time without rain, tied the previous record set in 2003 for a rainless period for San Diego County since record keeping began in 1850 (National Weather Service).

We have documented *S. hammondii* breeding in Dec in 1996, Nov and Dec in 2002, and Oct in 2004. In an extended literature search, we determined that these observations reported herein appear to be the earliest breeding records reported for *S. hammondii*. Additional records for *S. hammondii* larvae (ca. 10–12 mm) occurring in January include observations made in vernal pools in Carmel Mountain Preserve in 2003 and 2004 (32°43'17"N, 116°56'56" W, 95 m elev.) and in a road rut in the San Diego National Wildlife Refuge in 2003 (32°43'17"N, 116°56'56"W, 95 m elev.), San Diego County, by Carlton Rochester and Pete Famolaro.

We thank Norm Scott and Kathie Meyer for providing comments and Jens Vindum of California Academy of Sciences for providing museum numbers. Thanks to Naomi Ervin and Tim Cass for their field assistance. *Spea hammondii* egg masses and larvae were collected under California Department of Fish and Game Permit 5399. Larvae were collected from Mission Trails Regional Park under the authority of Paul Kilburg, Senior Park Ranger.

TESTUDINES

CHELYDRA SERPENTINA SERPENTINA (Common Snapping Turtle). **FLATULENCE**. On 19 June 2004 at ca. 1100 h, a female *Chelydra serpentina* (263 mm carapace length, 205 mm plastron length, 4082 g) was captured from an oxbow of Muddy Creek (0.30 ha mean surface area) at the Blue Grass Army Depot, Madison County, Kentucky (N37°42'15.5", W84°12'50.4"). As measurements were being taken of the animal, it released an audible gaseous discharge from its cloaca, accompanied by an unpleasant odor. No fluid was released during the discharge, but the sound it made was comparable to that of the characteristic hiss often given by this species when threatened. The odor was different from the typical musky odor released by this species, but was of equal severity. This behavior was accompanied by commonly-observed defensive behaviors in *C. serpentina*: snapping, gaping, hissing, and clawing (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, D.C.). The turtle was marked and released, and was not recaptured during subsequent trapping.

Flatulence in this case may have resulted from one of several factors. It may have been a displacement behavior, much like penis extrusion, which is often observed when male *C. serpentina* are handled (de Solla et al. 2001. Chelon. Cons. Biol. 4:187–189, pers. obs.). It may have been an intentional alternative to releasing musk, indicating a defensive behavior. Or the turtle may have had excess gas production due to something that it ingested. Such gas may have been released because of muscle contractions associated with the stress of handling, or because of a change in the pressure of internal organs on the intestines due to the position in which the turtle was held, or the gas release may have been coincidental with the time of capture. This apparently represents the first published account of flatulence in *C. serpentina*.

CHRYSEMYS PICTA PICTA (Eastern Painted Turtle). **PREDATION.** On 22 January 2005, KED et al. found desiccated remains of a juvenile *Chrysemys picta picta* inside a Wood Duck nest box (Yates Millpond, ca. 6.8 km N of McCullers [35º43'07"N, 78º41'11"W], Wake County, North Carolina, USA) that was occupied by an adult Eastern Screech-owl (*Otus asio*). The turtle measured 51 mm in carapace length and 47 mm in carapace width. Scratches were present on the plastron and the left hind foot was missing, strongly suggesting predation by the owl. The head and remaining limbs were essentially intact.

Several raptor species have been reported as occasional predators of *C. picta* and other turtles (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press. Washington, DC. 578 pp.). Browne (2002. Herpetol. Rev. 33:132) reported an attack on a juvenile *C. p. picta* by a northern harrier. Reports of owls taking turtles as prey are relatively few (Johnsgard 1988. North American Owls. Smithsonian Institution Press. Washington, DC. 295 pp.). To our knowledge, this represents the first report of predation on *C. picta* by a screech-owl.

GLYPTEMYS (= CLEMMYS) MUHLENBERGII (Bog Turtle). **FECUNDITY.** On 12 June 2003, while surveying two populations of Bog Turtles, *Glyptemys (Clemmys) muhlenbergii*, with New York State Department of Environmental Conservation personnel, 21 turtles were located. Of these, 18 (85.7%) were of the 7–13 yr old cohort, which is much higher than what would have been expected. This age group cohort coincides with the rabies epidemic which reached this area of Dutchess County, New York in 1990 (www.dec.state.ny.us/website). On 6 May 2004, these two populations were again surveyed and two additional populations close by were also surveyed. Of the 20 located turtles, 12 were

new turtles (not recaptures); of these, 11 (91.7%) were of the 7–13 yr old cohort.

It is inviting to speculate that the higher than expected cohort density of *G. muhlenbergii* might reflect reduced predation of turtles and eggs by mammalian predators such as Raccoon (*Procyon lotor*), Striped Skunk (*Mephitis mephitis*), foxes (*Vulpes fulva* and *Urocyon cinereoargenteus*), and Coyote (*Canis latrans*), as the number of these predators has been reduced because of a reduction of numbers in their populations from the rabies virus. Hypothetically this would increase turtle recruitment and yield skewed population dynamics similar to our findings.

GLYPTEMYS INSCULPTA (North American Wood Turtle). **TERRESTRIAL MOVEMENT.** Although long distance travel along waterways by *Glyptemys insculpta* has been reported (Quinn and Tate 1991. J. Herpetol. 25:220–222), published accounts indicate that terrestrial movement is conservative and within 150–300 m of the watercourse (Harding and Bloomer 1979. Bull. New York Herpetol. Soc. 15[1]:9–26; Arvisais et al. 2002. Can. J. Zool. 80:402–408; Tuttle and Carroll 2003. Chelonian Cons. Biol. 4:656–663). In 2000–2002, we radio-tracked *G. insculpta* in three Delaware River tributaries in Delaware Water Gap National Recreation Area. The longest axes of movements were observed to be 200–600 m and similar to those previously reported within the study region (Kaufmann 1995. Copeia 1995:22–27). In the populations studied, terrestrial movements were typically within the bounds of the aforementioned studies except for those of pre-nesting females which we observed to move randomly > 600 m an evening, while searching for nesting sites in agricultural fields.

The long-range terrestrial movement of one of our females is especially notable. This turtle (CL = 177 mm; 810 g; missing LF foot) was first captured and shell notched on 2 May 2000 in a stream (122 m elev.) ca. 400 m from its confluence with the Delaware River. Subsequently, this turtle was recaptured five times near the original capture site and then was radio-tagged in April 2002 and followed weekly. On 4 June 2002, the turtle was relocated 373 m from its previous streamside capture point in an upland meadow. Despite an exhaustive search, the signal was not heard again. On 8 June 2004, the female was recaptured at the edge of a marsh (213 m elev.) in the headwaters of a different stream system on private property 3.9 km SSE of the original capture site. Second growth woodlands, old fields, a highway, and pocket marshlands are found between the previous capture points and the 2004 recapture point. The female was palpated and determined to be gravid and assumed to be searching for a nesting site. This is a possible example of gene flow promotion between different populations (Kiester et al. 1982. Evolution 36:617–619).

We appreciate the assistance of radio-trackers Melissa Stepek and Stanley Boder. We too thank Tony Gonzalas for examining the turtle and the long-dead transmitter affixed to its shell, deciphering the information on its face, and contacting the investigators. The study was completed under National Park Service/Wildlife Conservation Society Cooperative Agreement with special assistance provided by Jeffrey Shreiner.

CASTELLANO**, Department of Biological Sciences, Fordham University, 441 East Fordham Road, Bronx, New York 10458, USA (e-mail: expansa@aol.com).

GLYPTEMYS INSCULPTA (North American Wood Turtle). **NEST INVADING PLANTS.** The failure of *Malaclemys terrapin* nests as a consequence of beachgrass (*Ammophilia breviligulae*) root encapsulation of eggs is well known (Lazell and Auger 1981. Copeia 1981:723–724; Stegmann et al. 1988. Can. J. Bot. 66: 714–718). Although plant species were not identified, root encapsulation was also reported to cause partial failure of *Emydoidea blandingii* nests (Congdon et al. 2000. Chel. Cons. Biol. 3[4]:569–579). And, sea oats (*Uniola paniculata*) has been implicated in the loss of 5.3% of the eggs of a Loggerhead Seaturtle (*Caretta caretta*) population (Caldwell 1959. *In* Caldwell and Carr. Bull. Florida State Mus., Biol. Sci. 4:319–348). In this last instance, the eggs were described as desiccated, with eroded shells, and invaded by roots in some cases. In 2001–2002, we studied the nesting habits of female *Glyptemys insculpta* in cornfields along the Delaware River in Warren County, New Jersey. Thirty-one nests were located and monitored. Of these, plants invaded two nests. In the first case, the roots of smooth crabgrass (*Digitaria ischaemum*) completely filled the nest chamber and enveloped all 7 eggs in the clutch. The roots of carpetweed (*Mollugo verticillata*) encapsulated 3 of 4 eggs in a second nest. One hatchling *G. insculpta* successfully emerged from the second nest. In both cases the encapsulated eggs were completely desiccated, badly eroded, and invaded by rootlets. It was not possible to determine if the eggs in these clutches were fertile, but 4% of the 228 eggs in the 31 nests were affected by root encapsulation. This observation represents another example of turtle nest invasion by plants. This mortality factor may be more significant than the current literature suggests.

We thank Daniel Atha of the New York Botanical Gardens for assistance in identifying the plant species. The study was completed under National Park Service/Wildlife Conservation Society Cooperative Agreement with special assistance provided by Jeffrey Shreiner and Larry Hilaire.

GLYPTEMYS INSCULPTA (North American Wood Turtle). **ATYPICAL SCUTES AND ANOPHTHALMIA.** Atypical scute formation in chelonians is a commonly reported anomaly. Of 2,220 turtle specimens examined in the Chicago Field Museum, 43% had anomalous scute arrangements (Zangerl and Johnson 1957. Fieldiana: Geology 10:341–362). The majority of these arrangements had either more or fewer scutes than the standard number.

In a series of 243 *Malaclemys terrapin* specimens examined (Coker 1910. J. Morphol. 21:1–75), 24% had more or fewer scutes than normal. Aside from scute irregularities, abnormalities of the head, including anophthalmia (eyelessness), are the most numerous terata evident among advanced turtle embryos incubated under laboratory conditions (Ewert 1979. *In* Harless and Morlock [eds.], Turtles: Perspectives and Research, pp. 333–413. John Wiley and Sons, New York). Anophthalmia however does not seem to be a common phenomenon among wild turtles (Mausolf and Wunder 1974. Copeia 1974:548–550). Presumably this condition would negatively affect hatchling survival in the wild, whereas scute irregularities are not considered lethal. In 2001–2002, we studied nesting success of *Glyptemys insculpta* in cornfields along the Delaware River in Warren County, New Jersey. Ninety-two hatchlings from 20 nests, as well as 12 hatchlings found in the agricultural fields during the study, were examined for developmental abnormalities.

Irregularities in carapacial scute formation and arrangement were observed in seven individuals (6.7% of specimens). Of these, three exhibited a reduction in marginal scutes (11 right or left instead of 12) and one exhibited a supernumerary (13 right) marginal scute. Of the others, the fourth left costal scute extended between the fourth and fifth vertebrals in one individual, another exhibited "dovetail syndrome" (Ewert 1979, *op. cit.*) with eight vertebrals, and the last individual emerged with the fourth neural bone exposed. Additionally, an anophthalmic hatchling, of normal size and shell conformation, was found. Facial and maxillary bones were reduced and pinched. Eye-slits were not present, and the globes and bony elements that normally support them were missing. This individual displayed no visual ability. Although not previously reported in wild specimens, anophthalmia has been reported in *G. insculpta* that were hatched from eggs incubated under laboratory conditions (Ewert 1979, *op. cit.*).

It appears that the external abnormalities we observed are comparable to those reported elsewhere for turtle hatchlings associated with natural nests (Walde 1998. Unpubl. Ph.D. dissertation, McGill University, Quebec; Standing et al. 2000. Chelonian Cons. Biol. 3:661–664). Abnormalities in hatchling composition are most often attributed to thermal and hydric stressors present during incubation (Gutzke et al. 1987. Herpetologica 43:393–404). However, the hatchlings noted here emerged from nests located in agricultural fields that have been farmed for hundreds of years and exposed to various pesticides and fertilizers over the past century; thus a hypothetical relationship between external anomalies and chemical exposure would be a worthy topic for future research.

Submitted by **CHRISTINA M. CASTELLANO**, Department of Biological Sciences, Fordham University, 441 East Fordham Road, Bronx, New York 10458, USA (e-mail: expansa@aol.com); and **JOHN L. BEHLER**, Department of Herpetology, Wildlife Conservation Society, 2300 Southern Boulevard, Bronx, New York 10460-1099, USA (e-mail: jbehler@wcs.org).

KINOSTERNON SONORIENSE (Sonoran Mud Turtle). **DIET.** Hulse (1974. J. Herpetol. 8:195–199) concluded from an examination of stomach contents that *Kinosternon sonoriense* was an opportunistic carnivore that fed mainly on invertebrates, though plants, fish, and ranid frogs were occasionally eaten. Ligon and Stone (2003. Herpetol. Rev. 34:241–242) reported two observations of *K. sonoriense* feeding on adult *Bufo punctatus*. Here, we add a reptile and a bird to the list of dietary items consumed by *K. sonoriense*. Both observations were made in small pools in the Peloncillo Mountains, Hidalgo Co., New Mexico (USA), in the same canyon as the observations reported by Ligon and Stone (*op. cit*.).

On 7 August 2004, at ca. 1000 h, we observed an adult female *K. sonoriense* (101.7 mm midline carapace length [MCL], 151 g) capture and kill a Black-necked Gartersnake (*Thamnophis cyrtopsis*, 348 mm SVL, 23.3 g). The observation began when we noticed splashing in a pool (ca. 12 m^2 area, ca. 10 cm deep) beside the trail. When first observed, the turtle's jaws held the snake by the neck, ca. 10 cm behind the snake's head. During the first 10 sec of the encounter, the snake attempted to bite the turtle on the carapace at least twice. Within two minutes, the snake was dead and the turtle was eating the snake. At this point the turtle appeared to notice us and released the snake, moving away from us toward the edge of the pool. We then captured and measured the turtle and collected the snake. The skin had been stripped off the dead snake from the point where the turtle had grasped the snake forward to the head, and there was a large piece of neck muscle missing. We released the turtle and deposited the snake in the University of Central Oklahoma Collection of Vertebrates (UCO 1001).

On 10 August 2004, at ca. 1800 h, we encountered an adult male *K. sonoriense* (114.5 mm MCL, 169 g) in a small pool (ca. 1 m^2 area, ca. 15 cm deep) with a dead Mockingbird (*Mimus polyglottos*). The intact, feathered head and wings of the bird were floating on the water surface. Below the water surface was the bird's skeleton, which had been picked nearly clean of soft tissue. The turtle had bird flesh on its face and foreclaws. After we identified the turtle, we photographed the bird and observed the turtle feeding on scraps of the bird that had settled to the bottom of the pool. We do not know how the bird died and are uncertain as to whether our observation involved predation or scavenging.

Mud turtles are common in shallow pools in our study area (Stone 2001. Southwest. Nat. 46:41–53). The obvious benefits of inhabiting these pools include hydration and opportunities to eat invertebrates, which are common in pools. Our observations, coupled with those of Ligon and Stone (*op. cit.*), suggest that pools might provide opportunities for mud turtles to eat relatively large vertebrates, and that vertebrates might be more important to the diet of *K. sonoriense* than previously thought.

We thank J. Hellack and W. Radke for identifying the bird from photographs. We thank the College of Graduate Studies & Research at the University of Central Oklahoma for financial support. This study was conducted under permits issued by the New Mexico Department of Game and Fish (Permit #2905) and the U.S. Forest Service (Authorization ID: SUP0080).

Submitted by **PAUL A. STONE, MARIE E. BABB, BRIAN D. STANILA, GERALD W. KERSEY,** and **ZACHARY S. STONE**, Department of Biology, University of Central Oklahoma, Edmond, Oklahoma 73034, USA (e-mail: pstone@ucok.edu).

MACROCHELYS TEMMINCKII (Alligator Snapping Turtle). **DIET**. Feces from a male *M. temminckii* (52 cm carapace length

[CL]; 55.9 kg) captured by L. Allen and M. Lepori in the Trinity River off Collins Avenue (#157), 3.0 miles N of I-30, in Arlington, Tarrant Co., Texas (USA) on 28 September 1993, were collected over the week after capture, and the vertebrate components were sorted and identified. This sample included skeletal and scute elements from one juvenile Red-eared Slider (*Trachemys scripta*) (estimated carapace length = 145 mm), shell elements of a juvenile Spiny Softshell (*Apalone spinifera*) (estimated CL = 15 cm), and three unrelated items made of black rubber. A few additional bony elements of these turtle species may have represented additional individuals.

Although turtles (including *T. scripta*) have previously been reported in the diet of *M. temminckii* (Sloan et al. 1996. Chelon. Conserv. Biol. 2[1]:96–99, and references therein), this report represents the first record for a softshell turtle and documents the ingestion of inanimate objects. Furthermore, the presence of three different items made of rubber suggests that they were obtained by active foraging. This supports the hypothesis (e.g., Spindel et al. 1987. J. Morphol. 194:287–301) that large Alligator Snapping Turtles will seek food by active foraging in addition to lingual luring.

Submitted by **JOHN B. IVERSON**, Department of Biology, Earlham College, Richmond, Indiana 47374, USA; and **RICK HUDSON**, Ft. Worth Zoological Park, Fort Worth, Texas 76110, USA.

PALEA STEINDACHNERI (Wattle-necked Softshell). **SIZE.** The published record straight line carapace length (SCL) for the Asian softshell turtle, *Palea steindachneri*, is 42.6 cm (Ernst and Barbour 1989. Turtles of the World. Smithsonian Institution Press, Washington, D.C., 313 pp.).

Two very large softshell turtles were found alive in an alley near the establishments of dealers in turtle and snake meat inside the city of Hong Kong, and brought to the junior author for identification. Each had the clusters of wattles at the base of the neck unique to *P. steindachneri* (Ernst and Barbour 1989, *op. cit.*). Both turtles weighed 25.4 kg when first received (one alive, one dead). The larger of the two exceeds the reported record length of the species with a SCL of 44.5 cm. Other measurements of this individual are: greatest carapace width, 40.8 cm; shell depth at the level of the forelimbs, 13.0 cm; total length (tip of snout to tip of tail), 86.0 cm; plastron length, 30.5 cm; plastron width at the bridge, 38.0 cm; bridge length, 7.0 cm; dorsal length of the stretched head and neck, 28.0 cm; greatest head width, 13.5 cm; mandibular length, 11.0 cm; neck length from occiput to anterior rim of carapace, 11.0 cm; total tail length, 7.6 cm; and basal tail width, 6.5 cm. Although not sexed, the size of the turtle probably indicates that it is a female. The specimens are in the collection of the junior author.

Palea steindachneri ranges naturally in China from Guandong and Guangxi provinces westward to Yunnan and Guizhou provinces, and also on Hong Kong and Hainan islands (Zhao and Adler 1993. Herpetology of China. SSAR Contributions to Herpetology 10). On Hong Kong Island, it occurs at the Byewash Reservoir of the Kowloon Reservoirs Group (Karsen et al. 1986. Hong Kong Amphibians and Reptiles. Urban Council Publications, Hong Kong, 136 pp.), but these two turtles were probably brought to the city from the mainland of China to be sold in the markets, and then escaped. It is unfortunate that the origin of the two *P. steindachneri* is unknown.

PSEUDEMYS GORZUGI (Rio Grande River Cooter). **RETICULATE MELANISM.** Increasing melanistic pigmentation with aging is well known in deirocheline turtles, particularly male *Trachemys scripta* and some *Pseudemys* (Ernst et al. 1994. Turtles of the United States and Canada, Smithsonian Inst.). However, reticulate melanism (RM), a netlike or vermiculate pattern of black markings that replaces the normal carapacial markings, has only been described in two subspecies of *Chrysemys* (Ernst et al., *op. cit*.; Smith et al. 1969. J. Herpetol. 3:173–176; Ultsch 1999. Herpetol. Rev. 30:225). Here, we report the occurrence of this pattern in *P. gorzugi*.

Though termed as a type of melanism, RM is not similar to the melanism reported in *Trachemys* (Tucker et al. 1995. J. Herpetol. 29:291–296). In *Trachemys*, melanism results in an almost completely black coloring of the carapace and significant darkening of the plastron. We completed extensive surveys of the turtle fauna in the Pecos and Devils River drainages of Texas from 2001–2005. During that study we documented RM in *P. gorzugi*, similar to the pattern reported in *Chrysemys*, with retention of the red carapacial coloration but with the pattern significantly broken by the invasion of black vermiculations. The marginal scutes of the plastron exhibit the same color change pattern but the central plastral scutes do not darken.

The pattern changes seen in *P. gorzugi* appear to be correlated with the age and sex of the specimen. Thus far, we have observed this pattern only in large adult males. In fact, this size-correlated color pattern change has only been observed in the largest 15% of the adult males encountered (N = 124, mean carapace length = 20.0 cm, SD = 5.0). Based on these values, males with carapace lengths at least one standard deviation greater than the mean, in this case, those males with carapace lengths ≥ 25.0 cm, display evidence of these changes in phenotype.

Reticulate melanism has not, to our knowledge, been reported in any other species of *Pseudemys*. In the hundreds of individuals of *P. texana* collected from Spring Lake (TSU Dept. of Biology survey data) and the San Marcos River (Caldwell and Hays counties, Texas; MRJF survey data), none of the specimens show evidence of this color pattern change. Thus, RM observed in large adult male *P. gorzugi* could indeed be a unique trait that further supports the monophyly of the species.

STERNOTHERUS ODORATUS (Common Musk Turtle). **CLUTCH SIZE**. Typical clutch sizes in *Sternotherus odoratus* range from 1 to 9 eggs (Ernst et al. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington and London. 578 pp.) and in the Jersey and Calhoun county populations in Illinois the clutch size averages 5.8 eggs (Tucker 1999. Bull. Maryland Herpetol. Soc. 35(3):61–75). On 11 May 2003, a gravid female *S. odoratus* (130 mm carapace length, 85 mm carapace width, 57 mm carapace height, 98 mm plastron length, and a gravid mass of 370 g) was collected crossing IL Rt 100 near Grafton, Illinois in Jersey County. Oviposition was induced via intramuscular oxytocin injection (Ewert and Legler 1978. Herpetologica 34:314–318). This female produced 13 eggs, exceeding all previous reports for this species from any population. The eggs averaged 4.06 g in mass, 26.1mm in length, and 15.9 mm in width. These eggs were incubated in vermiculite at ambient environmental temperatures and hatched between 24–26 August 2003. *Sternotherus odoratus* is suspected of communal nesting with more than one turtle laying their eggs in the same place (Ernst et al. 1994, *op. cit.*) Intermingling of separate clutches from more than one individual is possible and might obscure field observations of clutch size. The laboratory induction of oviposition eliminates this bias.

LAMER**, Department of Biological Sciences, Western Illinois University, 1 University Circle, Macomb, Illinois 61455, USA (e-mail: jthos50@hotmail.com).

STERNOTHERUS ODORATUS (Common Musk Turtle) **SIZE and REPRODUCTION**. The seminal work of Tinkle (1961. Ecology 42:68–76) on clinal variation in turtle reproduction addressed *S. odoratus*, and subsequent study showed that local variation could distort putative geographic patterns (e.g., Gibbons. 1970. Can. J. Zool. 48:881–885). Local variation in the reproduction of *S. odoratus* occurred in Indiana (Clark 2000. Unpubl. Ph.D. Thesis, Indiana University, Bloomington). This note documents maximum sizes of three natural history parameters for *S. odoratus* from three geographically separated fish farms. These farms consisted of many adjacent shallow (~0.5–1 m deep) ponds that were drained and refilled asynchronously. Most data came through oxytocin-induced oviposition or dissection.

The largest turtle (CM 154456; measurements in mm: 150 Mx CL, 125 Mx PL, 103 CW, 66 SH; 626 g live mass, nongravid female) came from a goldfish farm (Indiana, Morgan Co., Grassyfork Hatchery, 39.47°N, 86.36°W, 27 May 1993, collected by J. M. Capler and M. A. Ewert). The mid-dorsum of the carapace was slightly depressed relative to its immediately lateral curvature. The head had bold, bright stripes typical of young adult *S. odoratus*. The carapace length of this individual exceeded the published record of 137 mm (Conant and Collins 1991. A Field Guide to Reptiles and Amphibians: Eastern and Central North America [3rd ed.], Houghton-Mifflin, Boston).

Table 1 lists 11 clutches (from Indiana, *op. cit.*; another goldfish farm, Alabama, Marshall Co., Big Spring Farm, 34.22°N, 86.41°W; a natural lake, Wisconsin, Washington Co., 43.41°N, 88.22°W) that exceed the long standing record (nine eggs, Risley 1933. Pap. Michigan Acad. Arts, Sci. Lett. 17:685–711). The largest clutch (12 eggs), although partially destroyed during oviposition, was represented by 12 large (5–6 mm diam) ovarian corpora lutea. The same ovaries included nine small (2.5–3 mm diam) corpora lutea from a previous clutch and 11 enlarged (13–14 mm dia), preovulatory follicles. The RCMs of these turtles (Table 1) were much larger than in other kinosternids (Iverson et al. 1991. J. Herpetol. 25:64–72). Ten additional turtles from the two goldfish farms yielded nine-egg clutches (7 from Indiana, 3 from Alabama).

The largest egg (7.63 g, 33.7 × 18.7 mm), from Indiana (*op. cit.*, 28 May 1994), from a female (116 mm CL, 279 g FSM), was normally elongate (l/w =1.8, Clark et al. 2002. Funct. Ecol. 15:70–77), but did not develop. This egg was accompanied with four other eggs of normal size (4.5–4.6 g). The largest egg that has hatched (6.85 g, 30.3 × 19.0 mm) was part of a clutch of eight large eggs (5.5–6.9 g) from a female (128 mm CL, 315 g FSM) from Arkansas (Garland Co., Lake Hamilton State Fish Hatchery, 34.41°N, 93.06°W, 20 May 1989).

Which practices, if any, on fish farms enable female *S. odoratus* to become large and evidently uniquely prolific remain unevaluated. Nonetheless, these data suggest that geographical studies of reproductive data on turtles need cognizance of habitat type.

I thank J. Capler, P. Clark, and C. Etchberger for assistance with collecting these turtles, and the Carnegie Museum of Natural History (C. J. McCoy) for access to turtles in his possession.

TERRAPENE CAROLINA CAROLINA (Eastern Box Turtle). **PREDATION.** Eastern Box Turtles are omnivores that take a wide range of plant and animal matter (Dodd 2001. North American Box Turtles. A Natural History. Univ. Oklahoma Press). Every summer, from 1990 to 2004, I used a series of 17 mist nets to capture breeding songbirds. Box turtles are common in my study site, which is within the Jug Bay Wetlands Sanctuary (38°46'N; 76°42'W), on the east shore of the Patuxent River in Anne Arundel County, Maryland. Mist nets are 12 m long × 2 m high and are stretched between tall poles in forest, stream floodplain, and along the edge of a tidal wetland. The lowest tier of the net is normally about 30 cm above the ground, but when a bird is captured in this part of the net its weight causes the net to sag. As a result, a songbird can become entangled on the ground. On three occasions I have observed an Eastern Box Turtle eating a songbird that had been captured in a mist net.

On 29 June 1991, a turtle devoured an adult female Acadian Flycatcher (*Empidonax virescens*; USFWS band No. 1830-75071). On 25 June 1996, I observed a turtle eating a Red-eyed Vireo (*Vireo olivaceus*; unbanded). The vireo was dead, partially eaten, and the turtle had blood and feathers on its face. On 1 July 2003, I observed a turtle eating an Ovenbird (*Serius aurocapillus*; unbanded). The left wing was missing all tertial and secondary flight feathers and most primary feathers. The wings and body were bloody and bird could not fly. The turtle's mouth was filled with feathers. At my approach the Ovenbird escaped but probably did not survive the attack.

In each incident, the songbird had been initially captured in the lowest part of the mist net and was unable to escape when the turtle attacked it. Box Turtles probably capture and eat small healthy vertebrate animals only under unusual circumstances. Legler (1960. Univ. Kansas Publ. Mus. Nat. Hist. 11:527–669) reports a *Terrapene* eating a bobwhite quail chick and Anton (1990. Bull. Chicago Herpetol. Soc. 25:143–144) reported one eating a house sparrow. Alsop and Wallace (1978. J. Tennessee Acad. Sci. 53:134) report box turtles eating songbirds that had been killed at a tall radio tower during migration. There are also reports of box turtles eating small mammals that had been captured in traps (Legler 1960, *op. cit.;* Metcalf and Metcalf 1970. Trans. Kansas Acad. Sci. 73:96–117). While predation on healthy adult songbirds is certainly rare, the nestlings of ground-nesting species could be vulnerable to opportunistic predation by these turtles.

Songbirds were captured for study under permit #09517-L issued by the U.S. Fish and Wildlife Service.

TESTUDO GRAECA (Spur-thighed Tortoise). **SIZE**. The maximum straight carapace lengths (SCL) of *Testudo graeca* previously reported for Morocco come from Admine, in the Souss Valley (30°13'N, 9°31'W; 70 elev.). In this region, females reach 226.2 mm and males 184.4 mm (Carretero et al., *in press*. Anim. Biol.). Although Souss Valley specimens have been assigned to the subspecies *T. g. soussensis*, recent studies on mtDNA (Harris et al. 2003. Rev. Esp. Herpetol. 17:5–9) and morphometrics (Carretero et al., *in press*) do not support a distinction from the nominal subspecies found elsewhere in Morocco. During a herpetological survey in several Moroccan localities, six extremely large specimens were found in Tagourast (Boulemane Province, 32°51'N, 3°52'W; 1130 m elev.) on 14 October 2003. Two females (236.4 mm and 248.6 mm) and one male (200.3 mm) exceeded the highest SCL values reported for Souss Valley specimens (Bayley and Highfield 1996. Chel. Cons. Biol. 2:36–42; Carretero et al., *in press*); another male measured 184.1 mm. To our knowledge the largest female represents the maximum size record of this species in nature for Morocco. Despite the low sample size, this population seems to be composed of adult individuals of large size (means: 181.8 mm males, 218.8 mm females, N = 3 in both cases). All tortoises were photographed and released after measuring. It is noteworthy that Admine and Tigueust are 750 km apart, occupy different climatic zones (littoral in Admine and continental with high thermal amplitude in Tagourast) at different altitudes and harbor different habitats (patchy open forest with irrigated cultures and dry steppe, respectively). Furthermore, the Tagourast population is the southeastern limit of the *T. graeca* range in Morocco (Bons and Geniez 1996. Amphibians and Reptiles of Morocco. AHE. Barcelona).

LACERTILIA

ANOLIS SMARAGDINUS (Bahamian Green Anole). **DISPERSAL**. Several factors seem to influence lizard dispersal (Massot and Clobert 2000. J. Evol. Biol. 13:707–719), yet it remains the focus of relatively limited study. Notably, little attention has addressed how the patch size of unsuitable habitat might impede dispersal. Hence, we provide an observation of *Anolis smaragdinus* from the Bahamas showing how a patch of unsuitable habitat might have influenced dispersal.

In October 1993, as part of an experimental study of interspecific interactions (Losos and Spiller 1999. Ecology 80:252–258), five adult *A. smaragdinus* (2 males, 3 females) were introduced onto a tiny (801 m^2) islet lacking lizards that was located SW of Georgetown, Great Exuma, Bahamas (23º25'N, 75º50'W). This islet is connected to another slightly larger one (943 m^2) by an isthmus of bare rock that is land positive for only about one half of the tidal cycle; this latter islet also originally lacked lizards but none were introduced to it. The minimum distance between vegetation on the two islets is 17.7 m. However, the edge of both islets is vegetated with *Rhachicallis americana* (Rubiaceae), a small plant (mean height = 0.29 m; range = 0.05–0.58 m, N = 45) that *A. smaragdinus* rarely uses (JBL and DAS, unpubl. data). Moreover, *A. smaragdinus*, which is rarely seen on the ground, typically occupies shrubby vegetation > 1 m in height (Schoener 1968. Ecology 49:704–726). The minimum distance separating habitat typically occupied by *A. smaragdinus* (i.e., bushes > 1 m in height) on the two islets is 49.8 m. When we returned a year later (October 1994), we found one adult male and two smaller

individuals (sex undetermined) in a brief (ca. 15 min) survey of the larger islet (as well as an estimated 10 individuals on the smaller island to which they had been introduced).

This observation indicates that typically arboreal anoles may disperse some distance on the ground to colonize vegetation patches lacking canopy contact, a rarely reported phenomenon (Hicks and Trivers 1983. *In* Rhodin and Miyata [eds.], Advances in Herpetology and Evolutionary Biology: Essays in Honor of Ernest E. Williams, pp. 570–595. Museum of Comparative Zoology, Cambridge, Massachusetts). We consider the alternate possibility, that *A. smaragdinus* independently colonized the larger islet over water from another source island or was brought there by humans, to be highly unlikely. These islets are in a remote area ca. 5 km from Great Exuma. Natural colonization is unlikely because we have never observed this species on a tiny remote islet of this sort except for populations that we introduced in over two decades of studying the distribution of anoles on hundreds of islands in the Bahamas. Moreover, Hurricane Lili exterminated the populations on both islets in 1996. Since then we have visited these islets about four times a year and never found this species. In addition, these diminutive islets hold little interest for locals or tourists; we never saw evidence that humans other than ourselves visited them.

ASPIDOSCELIS TIGRIS AETHIOPS (Sonora-Sinaloa Desert Whiptail). **HABITAT, BODY SIZE, and REPRODUCTION.** We present data on a population of *Aspidoscelis tigris aethiops* (= *Cnemidophorus tigris aethiops*; Reeder et al. 2002. Am. Mus. Novitat. 3365:1–61) sampled by JLE in 2004 at Estación Ortíz, Valle de Guaymas, municipality of Guaymas, Sonora, México (28°17'23.9"N, 110°43'0.8"W, elev. 103 m). Estación Ortíz, the most southerly continental locality and lowest elevation (see Vitt and Breitenbach 1993. *In* Wright and Vitt [eds.], Biology of Whiptail Lizards (Genus *Cnemidophorus*), pp. 211–243. Oklahoma Mus. Nat. Hist., Norman, Oklahoma) at which habitat, body size, and reproductive characteristics for *A. tigris* (*sensu* Walker 1983. Southwest. Nat. 28:1–8) have been assessed, is situated ca. 40 km from the Gulf of California in a relatively flat Sonoran Desert basin surrounded by rocky hills. Most of the habitat utilized by *A. t. aethiops* (*sensu* Taylor and Walker 1991. Copeia 1991:800–809) in Valle de Guaymas is dominated by plant associations of mesquite (*Prosopis* sp.), large cholla and prickly pear cacti (*Opuntia* sp.), and scattered creosote bush (*Larrea* sp.). Some of these associations are impenetrable to humans; however, patches of open substrate among the plants are utilized by whiptail lizards and other reptiles. Most individuals of *A. t. aethiops* analyzed in this study were collected near the town, where they were easily stalked in severely altered habitats characterized by open areas, sandy soil, and degraded vegetation. This subspecies was also abundant, but difficult to collect, away from the town on gravelly soil in dense vegetation at the base of the hills. No other species of *Aspidoscelis* was observed at Estación Ortíz.

Analyses of reproduction and body size in *A. t. aethiops* are based on dissections and measurements performed by JMW on 176 preserved specimens of this subspecies catalogued in the herpetological collection of Unidad de Biología, Tecnología y Prototipos (UBIPRO 12847–12859, 12865–12869 [22 July 2004]; 13155–13197, 13214–13328 [12–14 August 2004]). Data are presented by sex as ratios, ranges of variation, and/or means (to one decimal place) ± 1SE.

Numbers of males and females, respectively (in parens), by size (as 10 mm increments in SVL) in the pooled UBIPRO sample are 35–39 (1:2), 40–49 (1:3), 50–59 (4:14), 60–69 (34:37), 70–79 (44:20), and 80–87 (13:3). Chi-Square tests revealed that the 22 July 2004 sample was significantly male-biased (16:2; $\chi^2 = 4.7$, $P = 0.03$); however, no significant gender bias existed in the 1214 August 2004 sample (81:77, $\chi^2 = 0.01$, $P = 0.91$). Collections of *A. tigris* are well known to often have unequal sex ratios that reflect behavioral differences correlated with the reproductive cycle (Pianka 1970. Ecology 51:703–720; Burkholder and Walker 1973. Herpetologica 29:76–83). Dearth of females in our July sample may reflect most females carrying oviductal eggs during which time their more retiring behavior made them less visible to humans (see Pianka 1970, *op. cit.*). Conversely, nearly equal sex ratio in the August collection may reflect most females (N = 34) carrying yolked ovarian follicles 3.0–8.0 mm in diameter, during which time they continue to actively forage to support clutch development (see Pianka 1970, *op. cit.*); at that time few females (N = 7) had oviductal eggs (mean dimensions 8.3 × 15.1 mm). In the pooled sample of *A. t. aethiops*, the 43 gravid females have a SVL range of 60–81 mm. Sexual dimorphism in the Estación Ortíz population of this subspecies is indicated by the significantly different SVL means ($P < 0.05$) for all adult females (68.5 ± 0.73, range 60–81, N = 60) compared to all adult males (71.7 ± 0.71, range 60–87, N = 91) in the pooled sample and the 13:3 ratio of males to females in the 80–87 mm SVL range. Numbers of undamaged gravid females (as 10 mm increments in SVL) are 60–69 (27), 70–79 (13), and 80–81 (3). Clutch size range in 43 females is 1–4, mean 2.2 ± 0.09. The number of eggs per clutch in *A. t. aethiops* is positively correlated with SVL ($r = 0.66$, $P < 0.01$). In the SVL range of 60–73 mm, clutch size is 1 (N = 1), 2 (N = 33), and 3 (N = 1), and in the SVL range of 72–81 mm it is 2 (N = 1), 3 (N = 5), and 4 (N = 2).

The geographic distribution of no other species of whiptail lizard in North American deserts approximates the vast latitudinal range of *Aspisoscelis tigris*. Its range extends from Oregon and Idaho in the USA to Sinaloa State, México (Wright 1994. *In* Brown and Wright [eds.], Herpetology of the North American Deserts: Proceedings of a Symposium, pp. 255–271. Southwestern Herpetologists Soc. Special Publ. 5, Van Nuys, California.), which is roughly equivalent to the combined latitudinal limits of the Great Basin, Mohave, and Sonoran deserts. Ecological adjustments associated with the exceptionally high density for *A. t. aethiops* observed at Estación Ortíz by JLE (N = 176 collected in 4 days in 2004), based on a small clutch size, include a lengthy growing season (> 200 days), early reproductive maturity at a small body size in the second summer of life, and likely production of multiple clutches (see McCoy and Hoddenbach 1966. Science

154:1671–1672). In comparison, the much lower densities for *A. t. tigris* observed in the Snake River Valley in Canyon, Ada, Owyhee, and Elmore counties in southwestern Idaho (N = 243 specimens collected in > 20 days in 1967 and 1968; Burkholder and Walker 1973, *op. cit.*), the most northerly area (ca. 43°26'N) in which habitat, body size, and reproductive characteristics for this species have been assessed (Taylor et al. 1994. Copeia 1994:1047–1050), is based on a shorter growing season (ca. 150 days), maturation at a larger SVL in the third summer of life (SVL 69–75 mm), and annual production of single clutches of similar size.

We thank Harry L. Taylor, Department of Biology, Regis University, Denver, Colorado, for suggestions that improved the manuscript.

CTENOSAURA BAKERI (Utila Spiny-tailed Iguana). **PREDATION**. *Ctenosaura bakeri,* an endemic to the Isla de Utila (Islas de la Bahia, Honduras), dwells exclusively in mangrove swamp (Köhler 1995. Salamandra 31:93–106). Little information exists on its life history. Hence, here I present observations of predation on juvenile and adult *C. bakeri*.

At 1145 h on 3 September 1999, I observed a *Boa constrictor imperator* drop from a Black Mangrove tree, *Avicennia germinans*, on the inland mangrove edge near Iron Bound on the north coast of Utila (16°07'22"N, 86°54'16"W). The snake was in the process of constricting an adult female *C. bakeri* across its abdominal region. After the snake killed the lizard, prey and predator were collected to prevent ingestion. The iguana measured 192 mm SVL and 474 mm total length and had a mass of 235 g. The snake measured 1400 mm total length and was released at the site of capture after examination. Predation by the snake was photodocumented. A second case of predation was recorded at 1030 h on 6 June 2000 in the mangrove swamp at Big Bight Pond on the eastern part of Utila (16°06'20"N, 86°53'29"W). A Turkey Vulture (*Cathartes a. aura*) was observed grasping an adult male *C. bakeri* and flew away. The iguana, estimated at 700 mm total length, had been resting about 20 m from my point of observation on the exposed branch of a Black Mangrove tree.

At 0930 h on 22 June 2000, while checking the nesting sites at Iron Bound, a large (ca. 700 mm total length) male Basilisk (*Basiliscus vittatus*) was spotted among the beach vegetation. On approach, the basilisk started running over a distance of about 3 m and caught a freshly hatched *C. bakeri* (ca. 170 mm total length) that ran by and swallowed it head first.

At 1042 h on 31 July 2001, I observed a group of Great-tailed Grackles (*Quiscalus m. mexicanus*), consisting of the two adults and two immatures, enter the mangrove swamp at Iron Bound. During this summer dry season, water levels were low and no water was present in many places; at this time, juvenile *C. bakeri* usually remain among the mangrove roots. As I observed one of the adult grackles rummaging through the roots, I saw it hunt and kill 4 iguanas within 10 min. The prey items were fed to the immature birds, which swallowed the juvenile *C. bakeri* head first. Predation by the grackle was videotaped.

Published observations of predation on *C. hemilopha*, *C. pectinata,* and *C. similis* exist (e.g., Carothers 1981. Behav. Ecol. Sociobiol. 8:261–266; Mora 1987. J. Herpetol. 21:334–335; Ramírez-Bautista and Uribe 1992. Herpetol. Rev. 23:82), but these observations are the first records of predation on *C. bakeri*.

Martina Koch, Simone Mosbacher, and Florian Beck assisted in the field.

CTENOSAURA HEMILOPHA (Cape Spiny-Tailed Iguana). **REPRODUCTION.** *Ctenosaura hemilopha* is known from Baja California south of Loreto to the Cape region and Cerralvo Island (Grismer 2002. Amphibians and Reptiles of Baja California Including Its Pacific Islands and the Islands in the Sea of Cortés, University of California Press, Berkeley, 399 pp.). The purpose of this note is to provide information on its reproductive cycle from histological examination of gonads from museum specimens.

A sample of 10 males (mean SVL = 177 mm ± 43 SD, range: 119–233 mm) and 11 females (SVL = 173 mm ± 25 SD, range: 153–237 mm) was examined from the Museum of Vertebrate Zoology (MVZ), Berkeley; and the Natural History Museum of Los Angeles County (LACM), Los Angeles. Histological procedures follow Goldberg and Beaman (2003. Herpetol. Rev. 34:143). Testes from 2 males (LACM 51838, 129 mm SVL; LACM 51840, 127 mm SVL) collected 4–6 March 1969 were in recrudescence just prior to the start of spermiogenesis (germinal epithelium dominated by primary spermatocytes and spermatids). A testis from 1 male (LACM 51839, 192 mm SVL), collected 4–6 March 1969 was undergoing early spermiogenesis (seminiferous tubules contained small amounts of sperm). Testes from 2 males (LACM 128245, 222 mm SVL; LACM 128246, 207 mm SVL) collected 30 April 1978, and 1 male (LACM 128248, 233 mm SVL) collected 7 May 1978, were undergoing spermiogenesis (lumina of seminiferous tubules lined by spermatozoa; rows of metamorphosing spermatids present). Testes from 1 male (LACM 19360, 209 mm SVL) collected 4 July 1959, 2 males (LACM 9850, 119 mm SVL; LACM 9852, 149 mm SVL) collected 17–18 July 1960, and 1 male collected on 19 July 1977 (LACM 126586, 183 mm SVL) were regressed (seminiferous tubules contained spermatogonia and Sertoli cells; germinal epithelium was exhausted). Presence of males undergoing spermiogenesis in April–May suggests that *C. hemilopha* breeds during spring, before late summer as suggested by Asplund (1967. Amer. Midl. Nat. 77:462–475).

The ovary from 1 female (LACM 51837, 157 mm SVL) col-

lected 4–6 March 1969, was undergoing early yolk deposition (follicles contained a ring of basophilic yolk granules). Yolk deposition was further advanced in a second female (LACM 51836, 153 mm SVL) collected 4–6 March 1969, with a total of 13 follicles (5.8 mm ± 1.1 SD diameter). However, whether all follicles would have completed development is unclear. No yolk deposition was underway in 9 females (SVL, collection date in parens): LACM 94820 (155 mm, 29 June 1967), LACM 126585 and 126587 (237 mm and 155 mm, respectively, both 16 July 1967), LACM 19361 (195 mm, 12 August 1964), MVZ 11489 (170 mm, 22 August 1929), LACM 19358 (163 mm, 28 August 1961), LACM 94821 (173 mm, 14 October 1968), MVZ 11476 (165 mm, 15 October 1928), and MVZ 11482 (178 mm, 30 October 1928). These data support that in *C. hemilopha*, yolk deposition is completed some time in spring. Asplund (*op. cit.*) observed hatchlings of *C. hemilopha* in late August, suggesting that eggs were deposited in spring.

We thank D. Kizirian (LACM) and D. Wake (MVZ) for permission to examine specimens.

BEAMAN,** Section of Herpetology, Natural History Museum of Los Angeles County, Los Angeles, California 90007, USA (e-mail: heloderma@adelphia.net).

EUMECES FASCIATUS (Five-lined Skink). **HATCHLINGS**. Many aspects of the biology of *Eumeces fasciatus* are well known, but most data involve populations from the northern and eastern portions of its range. (e.g., McCauley 1939. Copeia 1939:93–95; Fitch 1954. Univ. Kansas Mus. Nat. Hist. Publ. 8:1–156). Further information regarding hatchling morphometrics is generally restricted to measurements of SVL and mass. For this reason, we report here on hatchlings from a nest found in southeast Texas.

On 4 July 2004, we discovered a nest of 11 intact eggs under an irregularly shaped porous limestone (28 cm wide × 39 cm long × 28 cm high) at the base of a pecan tree (*Carya illinoensis*) surrounded by mixed grasses and debris that nearly concealed the limestone. This site, in an abandoned pecan orchard, is now a wooded lawn near the town of Hull, Liberty County (30°11'24.3"N, 94°40'46.4"W: elev. 24 m). The nest chamber was dome-shaped, measuring ca. 10 cm wide × 15 cm deep × 3 cm high. The entrance to the chamber was a natural crevice in the stone that opened toward the tree. The nest ceiling was a concavity beneath the stone, whereas the substrate beneath the eggs was bare soil excavated to a slight depression. An adult female *E. fasciatus* (ca. 60 mm SVL) accompanied the eggs. When the stone was lifted, she huddled on top of the eggs, but did not flee, even as the stone was carefully replaced. Examination of the nest at 1100 h the next day revealed that the adult had left and two of the eggs were slit and empty. No evidence of the hatchlings existed nearby. The remaining 9 eggs were collected and reared in a sealed container on moist potting soil. Hatchlings were each weighed and measured within 12 h of hatching. Method of taking measurements follows Smith (1946. Handbook of Lizards, Lizards of the United States and Canada. Comstock Publishing Associates. Ithaca, New York. 557 pp.)

All eggs hatched between 6 and 8 July 2004. Morphometric data were recorded for each hatchling (Table 1.) Mean values were as follows: 26.8 mm SVL (SD = 0.6), weight of 0.4 g (SD = 0.02), 62.8 mm total length (SD = 1.5), 7.7 mm head length (SD = 0.2), 4.2 mm ocular head width (SD = 0.2), 10.0 mm forelimb length (SD = 0.5), and 2.2 mm hind limb length (SD = 0.6).

TABLE 1. Morphometric data for 9 *Eumeces fasciatus* hatchlings from Liberty County, Texas. SVL = snout–vent length, TTL = total length, HL = head length, OHW = ocular head width, FLL = forelimb length, HLL = hindlimb length.

Hatchling (mm)	SVL (g)	Weight (mm)	TTL (mm)	HL (mm)	OHW (mm)	FLL (mm)	HLL (mm)
1	26	0.36	59	7.5	4.2	10.3	10.9
2	27	0.40	62	8.0	4.6	9.2	13.0
3	26	0.42	64	7.8	4.3	9.5	12.4
4	27	0.42	64	7.8	4.1	10.7	12.4
5	27	0.41	62	7.4	4.1	9.6	12.1
6	27	0.40	64	7.8	4.1	9.6	12.2
7	26	0.41	63	7.9	4.2	9.7	13.0
8	27	0.41	63	7.8	4.2	10.5	12.0
9	28	0.42	64	7.3	4.1	10.5	12.1

The sizes (as SVL) and masses of these hatchlings are similar to those reported from Kansas (Fitch, *op. cit.*) and Maryland (McCauley, *op. cit.*). Data are lacking to compare remaining measurements. These data represent the first documentation of morphometric information for *E. fasciatus* hatchlings from the southwestern edge of its range.

Submitted by **CHARLES M. WATSON**, Department of Herpetology, The Dallas Zoo, 650 South R.L.Thornton Freeway, Dallas, Texas 75203, USA (e-mail: varanid@mail.com); and **JASPER C. WATSON,** Box 301, Daisetta, Texas 77533, USA.

GAMBELIA WISLIZENII (Long-nosed Leopard Lizard). **PREDATION**. Despite a broad distribution, few reports of *Gambelia wislizenii* predators exist. Based on stomach contents, Ortenburger (1928. Mem. Univ. Michigan Mus. 1:1–243) identified *Masticophis flagellum* as a common predator of *G. wislizenii*. To my knowledge, the only other predators noted to date are larger conspecifics (McCoy 1967. Am. Midl. Nat. 77:138–146; Montanucci 1967. Herpetologica 5:119–126). Here I provide an observation of domestic cat (*Felis catus*) predation on *G. wislizenii* from southeastern Oregon.

Around 1000 h on 28 June 2003 on the west edge of the Alvord Desert in the hamlet of Fields, Harney Co. (42º15.8'N, 118º40.5'W; elev. 1290 m), I saw an average-sized *F. catus* pounce from the edge of an unidentified shrub into a patch of grass. When it lifted its head, the cat was holding an adult *G. wislizenii*, ca. 90 mm in snout-to-vent length and with no visible nuptial coloration, by the lizard's neck. The lizard was immobile and appeared to be dead. The cat lowered the lizard back to the ground and although the cat's mouth was not visible through the grass, its head and shoulders made movements indicative of the tearing apart and ingestion of prey. I observed the cat for ca. 2 minutes, at which point it was apparently still ingesting the lizard. This entire observation

occurred in a small patch of unidentified mixed shrubs and grasses between the east side of State Route 205 and a grove of trees surrounding a small pond, < 100 m from the nearest house.

Cats prey on a wide variety of animals, including lizards (Fitzgerald and Turner 2000. *In* Turner and Bateson [eds.], The Domestic Cat: The Biology of Its Behaviour, 2nd ed., pp. 151–175. Cambridge University Press, Cambridge). For example, cats take an estimated 2.9–9.4 million lizards annually in Virginia (Mitchell and Beck 1992. Virginia J. Sci. 43:197–207). Cats are also thought to have driven some lizard species extinct (e.g., Iverson 1978. Biol. Conserv. 14:63–73). However, this is the first record of cat predation on *G. wislizenii*, or any *Gambelia* species (Fitzgerald and Turner, *op. cit.*). Knowledge of predators of *G. wislizenii* is important because their predators are likely to be similar to those of the closely related and federally Endangered *Gambelia sila* (Tollestrup 1982. Am. Midl. Nat. 108:1–20). The potential impact of feral and free-ranging domestic cats should be considered in the management of *Gambelia* lizards.

HEMIDACTYLUS PLATYCEPHALUS (Flat-headed Tropical House Gecko). **REGIONAL INTEGUMENTARY LOSS**. Regional integumentary loss (RIL, *sensu* Bauer et al. 1989 J. Exp. Biol. 145:79–102), an anti-predator strategy complementary to tail autotomy, is reported for at least 10 genera of gekkonids (Bauer et al., *op. cit.*) and seems to evolve mainly in insular contexts (Bauer and Russell 1992. Ethol. Ecol. Evol. 4:343–358). Here, we add *Hemidactylus* to the list of genera that display this behavior and comment on the insular context.

During a field trip to the Comoro Islands (West Indian Ocean) in October–November 2003, MAC and DJH collected more than 50 *Hemidactylus* specimens by hand for genetic analysis from the four main islands (Mayotte, Grande Comore, Anjouan, and Moheli). More than the 90% of *H. platycephalus* spontaneously and systematically released part of the skin when handled (even if gently), without bleeding or any other apparent damage. In a second trip to Tanzania in October 2004, DJH and SR recorded similar observations for the same species in Zanzibar, Pemba, and the Tanzanian coast. Both insular and mainland populations of *H. platycephalus* showed RIL and genetic analysis did not reveal evidence for an insular origin of this species (Rocha et al. 2005. Mol. Phyl. Evol., in press). Remarkably, other members of this genus collected in similar numbers at the same sites (*H. brooki*, *H. frenatus*, and *H. mercatorius* in the Comoros; *H. mercatorius* in Zanzibar, Pemba, and mainland Tanzania) did not display such strategy. Because the distinction was congruent with the estimates of relationships based on DNA sequence data (Rocha et al., *op. cit*.), RIL could be used as another character to identify *H. platycephalus*, at least in this area. To our knowledge, this is the first report of RIL in *Hemidactylus*, although the skin of *H. fasciatus* has been described as thin and weak similar to that of gekkonids for which RIL has been reported (Bauer et al., *op. cit.*).

IGUANA IGUANA (Green Iguana). **NESTS and NESTING**. Widespread in tropical America, *Iguana iguana* occurs in a range of climates. Despite this broad-ranging condition, reproductive data are described for few populations (Alvarado et al. 1995. Southwest. Nat. 40:234–237; Bock and Rand 1989. Copeia 1989:978–986; Klein 1982. Brenesia 19–20:301–310; Rodda and Grajal 1990. Amphibia-Reptilia 11:31–39). *Iguana iguana* breeds seasonally throughout its range from Mexico to Brazil (Rand and Greene 1982. Iguanas of the World: Their Behavior, Ecology, and Conservation. Noyes Publ., Park Ridge, New Jersey), but reproductive data from Brazil are lacking. Here, we help fill this gap with preliminary data from northern Brazil.

During September–November 2001, we obtained data on some nests of *I. iguana* at Reserva Biológica do Rio Trombetas. The reserve, a 385,000-ha area located in the northwest part of state of Pará, municipality of Oriximiná, is on the northeast bank of Rio Trombetas (01°46'S, 55°52'W; elev. ca. 46 m). Nesting occurred in sand banks (tabuleiros) formed by dropping river water levels. Our data are based on five nests of *Iguana* discovered between 16 and 25 September at Tabuleiro do Farias and Tabuleiro do Jacaré. Based on regular surveys in the area, we estimated that nests were discovered ca. 10 days after egg laying. In order to limit predation on the nests following their disturbance, after recording the original position of each egg, we transferred the eggs to similar holes excavated in the same sand bank where they could be monitored continuously.

Nest dimensions (depth between the surface and incubation chamber, and the horizontal distance between the nest entrance and incubation chamber) were measured to the nearest centimeter. Egg data were obtained from two clutches measured immediately after their discovery using calipers to the nearest 0.05 mm and weighed to the nearest 1g with Pesola spring scales. We analyzed change in egg volume and mass in a 20-egg clutch between the day of initial measurements and the 70th day of incubation using a Wilcoxon signed rank test. Hatchlings were also measured (SVL) and weighed immediately after hatching.

Two nests were located in areas totally exposed to the sun; vegetation at least partially shaded the other three nests. Nest depth ranged from 30 to 120 cm (mean = 67.2 cm, s = 41.0) and distance between the nest entrance and incubation chamber from 100 to 463 cm (mean = 311 cm, s = 169). Clutch sizes were 20, 21, 22, 24, and 33. Mean egg length for the two clutches measured (33 and 20 eggs, data for each in this order hereafter) was 4.5 cm (s = 0.2, range: 4.2–5.0 cm) and 4.9 cm (s = 0.2, range: 4.7–5.3 cm), mean egg width was 3.4 cm (s = 0.1, range: 3.2–3.5 cm) and 2.9 cm (s = 0.1, range: 2.7–3.1 cm) and mean egg mass was 28.3 g (s = 0.9, range: 27.0–31.0 g) and 21.4 g (s = 0.9, range: 19.5–23.0 g). Increase in egg volume and weight during the incubation period was significant ($P < 0.01$ for both). Hatchlings (N = 6, all from first nest) averaged 7.2 cm SVL (s = 0.1, range: 7.1–7.3 cm), 19.9 cm tail length (s = 0.6, range: 19.0–20.5 cm), and 14.9 g in mass (s = 0.9, range: 14.0–16.0 g).

Rio Trombetas Green Iguanas laid larger clutches (mean = 24, range: 20–33, N = 5) than Green Iguanas from Curaçao, off the north coast of Venezuela (mean = 17 eggs, range: 10–31, N = 23; Fitch 1985. Misc. Publ. Mus. Nat. Hist. Univ. Kansas 76:1–76), but smaller clutches than those reported elsewhere in Mexico and Central America (means = 29.7–39.5, overall range: 13–60, N = 145; Alvarado et al., *op. cit*.; Fitch 1973. Univ. Kansas Sci. Bull. 50:39–126; Fitch 1985, *op. cit*.; Klein, *op. cit*.; Miller 1987. Zoo Biol. 6:225–236). Rand (1984. *In* Seigel et al. Vertebrate Ecology and Systematics: A Tribute to Henry S. Fitch. Mus. Nat. Hist., Univ. Kansas, Lawrence. 278 pp.) noted that clutch size increases with body size. Egg mass varied between our two monitored clutches but was greater than that reported for eggs from Mexico (mean = 15.2 g, range: 12.1–17.7 g; Alvarado et al., *op. cit*.). If a smaller clutch size as one nears the equator is a real trend, it may be related to an increase in mass of individual eggs. Size of Rio Trombetas hatchlings was also larger than that reported for Curaçao (mean = 6.6 cm, range: 6.2–6.8, N = 23; Bakhuis 1982. J. Herpetol. 16:322–325), similar to those reported for Michoacan (mean = 7.2 cm, range: 6.1–8.5, N = 327; Alvarado et al., *op. cit*.), but smaller than hatchlings from northern Colombia (range: 7.0–8.6; Rand and Greene, *op. cit.*). Variation we observed in size and weight of clutches and hatchlings may reflect variation in maternal size (Rand, *op. cit.*), but we lack data to test this hypothesis.

This work was carried out under IBAMA permits 173 - 99 and 013 - 2002.

IGUANA IGUANA (Green Iguana). **PREDATION.** *Iguana iguana* is exotic to Florida, but has been reported in the wild there since the 1960s, with breeding colonies reported since the 1980s (Meshaka et al. 2004. The exotic amphibians and reptiles of Florida, Krieger Publishing Company, Malabar, Florida, USA. 155 pp.). *Iguana iguana* is currently known to breed at diverse sites on the Florida mainland and in the Keys (Meshaka et al., *op. cit.*). As indigenous predators may represent one controlling influence on exotic Florida herpetofauna (Butterfield et al. 1997. *In* Simberloff et al. [eds.], Strangers in Paradise, pp. 123–138, Island Press, Washington, DC), we report here an observation of Yellow-crowned Night Heron (*Nyctanassa violacea*) preying on *I. iguana* from the Florida Keys.

At ca. 0800 h on 5 June 2004 (ca. 27°C air temperature), EMS observed a juvenile *N. violacea* that had just captured a hatchling (ca. 150 mm SVL) *I. iguana* by the old Bahia Honda Bridge in Bahia Honda State Park on Bahia Honda Key (24°39'17"N, 81°16'52"W; elev. ca 2 m). Based on size, the lizard had probably hatched the previous August (Meshaka et al., *op. cit.*).

The event was noteworthy not only because it involved another case of a juvenile wading bird foraging in a terrestrial situation and preying on an exotic species (Smith and Engeman 2004. Herpetol. Rev. 35:169–170), but because natural predators of *I. iguana* have not been recorded in Florida. Most foraging by *N. violacea* occurs in shallow water, with crustaceans the primary prey (Bancroft and Strong 1996. *In* Rodgers, Jr. et al. [eds.], Rare and Endangered Biota of Florida, pp. 450–456, University Press of Florida, Gainesville). Herons and egrets have been known to capture and consume exotic lizards in terrestrial situations (Franz 2001. Herpetol. Rev. 32:253; Smith and Engeman, *op. cit.*), but prior to this observation only dogs had been reported as predators on *I. iguana* in Florida (Meshaka et al., *op. cit.*). This is also the first observation of a hatchling *I. iguana* on Bahia Honda Key, although ES has observed adult *I. iguana* here for at least 5 yrs.

LEIOLOPISMA TELFAIRII (Telfair's Skink). **CAUDAL LURING**. Caudal luring is a technique employed by sit-and-wait foragers from a number of squamate lineages (e.g., Simon et al. 1999. Herpetol. Rev. 30:102–103), and typically involves the use of tail movement to attract potential prey within striking distance (Pough et al. 2004. Herpetology. Pearson Education Inc. New Jersey, 726 pp.). Among lizards, caudal luring has only ever been recorded in *Lialis burtonis* and was observed to occur only when the prey evaded an initial strike (Murray et al. 1991. Copeia 1991:509–516.). Here we report observations made during a field study that suggest that *Leiolopisma telfairii* might employ caudal luring as an opportunistic technique to enhance predation on other lizards.

Telfair's Skink, a historically common species throughout the island assemblage associated with Mauritius, has declined markedly because of ship-facilitated introduction of Black Rats (*Rattus rattus*), which has resulted in the species now being confined to Round Island, 22.5 km off the NE coast of Mauritius (Jones 1993. Proc. Roy. Soc. Art. Sci. Mauritius V:71–92). *Leiolopisma telfairii*, the largest living skink in Mauritius, attains a size over 160 mm SVL (Pernetta 2004. Microhabitat and Dietary Preferences of Telfair's Skinks (*Leiolopisma telfairii*): Implications for their Translocation. MSc thesis, University of East Anglia, Norwich, United Kingdom. 41 pp.). Fecal analysis of 59 individuals recorded 20 different food items and confirmed its omnivorous status (Pernetta, *op. cit*.). Evidence of saurophagy, in the form of scales and bones of Bojer's Skinks (*Gongylomorphus bojerii bojerii*), was recorded in three separate fecal samples and occurs from a young age (Fig. 1.).

While collecting data on *L. telfairii* ecology, we made observations of 3 adults (≥ 100 mm SVL) employing a novel behavior in attempting to capture Bojer's Skinks. On all three occasions (22 April, 15 May, and 1 June 2004), adult Telfair's Skinks had been observed making an initial unsuccessful attempt to capture adult (ca. 60 mm SVL) Bojer's Skinks. Despite the fact that an attempt at predation was made, the Bojer's Skinks remained within view of the pursuing *L. telfairii*. Each *L. telfairii* then stopped, curled their tail around until the tip was parallel to their head, and undulated the last ca. 5 cm of their tail several times while remaining

FIG. 1. A juvenile *Leiolopisma telfairii* (56 mm SVL) with an adult? *Gongylomorphus bojerii bojerii* (35 mm SVL) regurgitated during handling on Round Island, Mauritius.

otherwise motionless. Each Bojer's Skink exhibited an obvious attraction to the tail undulation and moved to within 10–15 cm of the Telfair's Skinks. Once within this distance, all the Telfair's Skinks made a lunge at the Bojer's Skinks, but no episode resulted in the successful capture of the smaller skinks.

Our observations of this behavior suggest that Telfair's Skinks might be using an opportunistic form of caudal luring similar to that employed by *Lialis burtonis*. Notably, *L. telfairii* exhibits few characteristics common among species that frequently employ caudal luring. Caudal luring has generally been associated with sit-and-wait foragers with differently colored tail tips (Pough et al. 2004, *op. cit.*). *Leiolopisma telfairii* is an omnivore that employs both sit-and-wait and active foraging modes (Pernetta, pers. observ.) and lacks variation in tail tip color. Saurophagy by *L. telfairii* is a deviation from the usual diet of arthropods observed among Scincidae (Greer 2001. J. Herpetol. 35:383–395), and might result from these island lizards broadening their diets to compensate for limited prey availability (Cooper and Vitt 2002. J. Zool. [London] 257:487–517). These observations constitute the second recorded use of caudal luring by a lizard and the first record of its use within Scincidae.

TEIUS TEYOU (NCN). **BEHAVIOR.** Arm or hand waving is considered a pursuit-deterrent signaling evolved in many teiid lizards (Cooper et al. 2004. Behavior 141:297–311). This behavior is undescribed in the genus *Teius*. Hence, we provide observations of hand waving in *T. teyou* from western Brazil.

Observations were made in rocky areas near the municipality of Corumbá, state of Mato Grosso do Sul (19º10'49"S; 57º32'17.2"W; elev. 117 m). From May 2003 to April 2004, we observed *T. teyou* perform hand waving behavior on 34 different occasions (juveniles, N = 14; subadults N = 11; adults N = 9). Hand waving in *T. teyou* consists of lifting and waving the forelimbs, alternating the arms. In almost all cases, the initial wave was made with the arm closest to the observer. Each time the behavior was performed, the lizard-observer distance was ≥ 2 m. The waving lizard fled if the observer approached rapidly or made abrupt movements. Lizards continued to wave as they moved away from the observer until they were ca. 5 m away; at that distance, they resumed normal foraging behavior.

In contrast to hand waving behavior in *Cnemidophorus murinus*, which waves primarily while stationary and uses only the foreleg closest to the investigator (*fide* Cooper et al., *op. cit.*), *T. teyou* typically wave their arms as they are moving away, ceasing waving at a presumptively safe distance. *Cnemidophorus lemniscatus* also waves preferentially with one arm, although both arms are occasionally used (Magnusson 1996. Herpetol. Rev. 27:60). Similar to species of *Cnemidophorus*, *T. teyou* waves their arms looking directly at the predator (the observer), implying that this behavior functions to signal predators.

SERPENTES

BOTHROPS ATROX (Common Lancehead). **MATING**. The mating season for *Bothrops atrox* in the Brazilian Amazon is poorly understood. Martins and Oliveira (1998. Herpetol. Nat. Hist. 6:78-150) reported two observations of mating in April for Adolph Ducke Reserve (40 km N of Manaus, Brazil) and Federsoni (1978/79. Mem. Inst. Butantan 42/43:159–169) reported a mating in captivity that lasted nearly 24 h. On 11 May 2004 (rainy season) at 0530 h we found a pair of *B. atrox* mating between the logs of a bridge over the stream Barro Branco at Adolph Ducke Reserve (02º55'S 59º59'W). The male was ca. 100 cm TL and the female was ca. 150 cm TL. We did not attempt capture them. A large lateral bulge just anterior of the female's cloaca evidenced intromission. When disturbed, the female moved into shallow water, dragging the male along. The pair was observed at one hour intervals for three hours, and were still mating when last observed at dusk (ca. 1800 h). On 31 January 2002 at ca.1600 h local people found a second pair *of B. atrox* mating in a secondary forest bordering Lake Cururu near the Solimões River and town of Manacapuru (03º32'36.6"S 60º42'30.7"W), ca. 90 km SW of Manaus. The locals reported that a dog, which attacked the mating snakes, died from envenomation. After the attack the snakes continued to mate until the locals killed them. Both the male (84 cm SVL) and female (122 cm SVL) were deposited in the Instituto Nacional de Pesquisas da Amazônia Herpetological Collection (INPA-H 11674 and 11675).

In both of these observations, the female was dark brown and

larger, while the male was lighter (yellowish) brown and smaller. Although sexual dichromatism has not been reported in *B. atrox*, it has been reported for closely related species such as adult *Bothrops moojeni* (Leloup 1975. Acta Zool. Pathol. Antverp. 62:173–201), juvenile *B. asper* (Burger and Smith 1950. Science 112:431–433), and newborn *B. jararacussu* (Marques and Sazima 2003. Herpetol. Rev. 34:62).

Submitted by **TÂNIA M. SANAIOTTI,** Coordenação de Pesquisas em Ecologia, Instituto Nacional de Pesquisas da Amazônia, Cx.P. 478, 69.011–970 Manaus, Amazonas, Brazil (e-mail: sanaiott@inpa.gov.br); **JULIO D. COLUBER CONSTRICTOR (Racer). **REPRODUCTION**. In many animal species a single mating is sufficient for reproductive success. Consequently, female reproductive success might not typically increase as a result of mating with multiple males (Barry et al. 1992. Behav. Ecol. Sociobiol. 30:193–199). Conversely, evidence from the European Adder (*Vipera berus*) suggests that multiple mating by females might benefit offspring viability (Madsen et al. 1992. Nature 355:440–441), and polyandry (and multiple paternity) have been reported from an increasing variety of snake taxa (Garner et al. 2002. Copeia 2002:15–23). Because it is generally thought that male snakes are unable to force copulations, behaviors such as multiple mating would be dictated by female choice (however see Shine et al. 2000. Behav. Ecol. Sociobiol. 48:392–401).

During the spring of 2004 in Rutherford County, Tennessee (USA), a radio tagged female *Coluber constrictor* was observed on four separate occasions either copulating with, or in close proximity to, three different males. On 28 April, she copulated with a telemetered male. The pair were joined for ca. two minutes before separating. On 4 May, the same female was observed copulating with a second male. The pair continued to copulate for ca. one minute before separating because of disturbance. On 8 May, the female was again located, and a third male *C. constrictor* was observed 3 m from the female's location. The male snake exhibited typical trailing behavior in the direction of the female. On 10 May, the female was located and found to be underground, and the telemetered male first observed mating with her on 28 April was within 10 cm of the opening of the hole she occupied. These observations demonstrate, for the first time, that the mating system of *C. constrictor* includes polyandry. These observations also suggest that males may court the same female multiple times.

Submitted by **J. JEFFREY GREEN** (e-mail: jjg2t@mtsu.edu) and **VINCENT A. COBB** (e-mail: vcobb@mtsu.edu), Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee 37132, USA.

COLUBER CONSTRICTOR CONSTRICTOR (Northern Black Racer). **BEHAVIOR.** Entanglement of snakes, including *C. constrictor*, in plastic netting has been documented by Stuart et al. (2001. Hepertol. Rev. 32:162–164) in terrestrial habitats. Robin Jung (pers. comm.) reported that in Shenandoah National Park, Virginia, 42 leaf litter bags in each of nine streams in a month-long sampling period yielded two dead Northern Watersnakes (*Nerodia sipedon*) and a dead Northern Green Frog (*Rana clamitans*). We used leaf litter bags (plastic netting; Pauley and Little 1998. Banisteria 12:32–36) to study streamside salamander communities in a small stream in Anderson County, Tennessee. We placed 18 litter bags in a first-order stream at the University of Tennessee Forestry Experiment Station and checked them twice a week from April through August for three seasons (2001–2003). During the second year of study, four adult *C. constrictor* were found on separate occasions (18 and 27 June, 18 and 23 July) entangled in separate leaf litter packs (963, 1045, and ca. 700 mm SVL; one unmeasured). Although each was unable to escape from the netting, only one was dead. One *Pseudotriton ruber* larva (35 mm total length) and one unidentified salamander larva (14 mm total length) were found alive in two of the litter bags after the snakes had been cut out of their bags.

These racers may have become entangled in the leaf litter bags while foraging for food. Ernst and Ernst (2003. Snakes of the United States and Canada. Smithsonian Inst. Press, Washington, DC, 668 pp.) describe *C. constrictor* habitat in the east as being dry with some water available nearby and noted that potential habitats are sometimes adjacent to swamps and marshes. Within the same study site described above, we have observed radio-tagged *C. constrictor* along stream margins, but have not found them foraging in streams. Mitchell (1994. The Reptiles of Virginia. Smithsonian Inst. Press, Washington, DC, 352 pp.) lists numerous prey of *C. constrictor*, including Northern Dusky Salamanders (*Desmognathus fuscus*), Northern Watersnakes (*N. sipedon*), and Common Gartersnakes (*Thamnophis sirtalis*). Besides this reference and Ernst and Ernst (2003, *op. cit.*), there are few records of racers preying on salamanders. Our single record of a live *N. sipedon* in a leaf litter bag on 7 June 2001 supplements Jung's observation (see above). Although stream foraging has not been described for *C. constrictor*, our capture records in stream litter bags, in conjunction with their catholic diet, suggest that racers may occasionally forage in water. Researchers using litter bags in streams to study salamanders should be aware of the potential danger to frogs and snakes.

We thank John Fauth, Joe Mitchell, James Stuart, Robin Jung, and Adam Leath for assistance. Clinch River Environmental Studies Organization (Department of Energy) provided funding.

CROTALUS ATROX (Western Diamond-backed Rattlesnake). **DIET**. Although mammals constitute the majority of prey items taken by *Crotalus atrox*, several reports have documented that birds represent a small percentage of their diet (Spencer 2003. Geographic Variation in the Diet, Morphology, and Reproduction of a Widespread Pitviper, *Crotalus atrox*. Ph.D. dissertation. Univ. Texas, Arlington, Texas. 177 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History, Univ. of

Texas Press, Austin. 372 pp.). The majority of bird predations have been documented from stomach content analysis (Beavers 1976. Southwest. Nat. 20:503–515; Spencer, *op. cit.*). Herein we report a previously undocumented bird species as prey for *C. atrox*.

At 1520 h on 12 October 2002 a small adult *C. atrox* (ca. 800 mm SVL) was observed striking, killing, and consuming an adult Western Meadowlark (*Sturnella neglecta*) along the Colorado River Aqueduct in Pinto Gap (ca. 8 km NE of the Eagle Mountain Pumping Plant), San Bernardino County, California (USA). The bird landed on a concrete bank within 0.3 m of the rattlesnake, which lay coiled under an adjacent Brittlebush (*Encilia farinosa*). The snake struck ca. 5 sec after the bird landed and held onto it for ca. 6 minutes before it was immobilized and ingested.

CROTALUS CATALINENSIS (Santa Catalina Island Rattlesnake). **DIET and MORTALITY.** On 19 April 2004 a thin, gray-phase male *Crotalus catalinensis* (580 mm SVL, 50 mm TL) was found dead under an Iron Tree (*Ebenopsis confinis*) on Isla Santa Catalina, México. An exceptionally large *Dipsosaurus catalinensis* (Cachorón Lizard; 130 mm SVL, 250 mm TL) was lodged in the snake's mouth and esophagus. Developmental stages of fly (*Sarcophaga* and *Cochliomyia*) larvae on the corpses suggest that death occurred approximately a week earlier. In addition, we have observed prey remains consistent with *D. catalinensis* in 13 of 83 (15.7%) scats obtained from *C. catalinensis* since 2003.

Examples of large snakes eating larger prey are common in the literature (e.g., Klauber 1982. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. Univ. of California Press, Berkeley, California. 350 pp.) and cost-benefit trade-offs associated with this behavior are addressed by Arnold (1993. *In* Seigel and Collins [eds.], Snakes: Ecology and Behavior, pp. 87–115. McGraw-Hill, New York.). This is the first published record of *D. catalinensis* in the diet of *C. catalinensis*, and the first observation of attempted ingestion of a seemingly fatal meal by *C. catalinesis*. Both predator and prey are endemic to Isla Santa Catalina (Grismer 2002. Amphibians and Reptiles of Baja California, Including its Pacific Islands and the Islands in the Sea of Cortés. University of California Press, Berkeley, California. 409 pp.).

CROTALUS VIRIDIS VIRIDIS (Prairie Rattlesnake). **DIET.** Many diet studies implicitly assume that items found in gastrointestinal tracts were taken alive, and the importance of carrion in the diet of some snakes might be underestimated (DeVault and Krochmal 2002. Herpetologica 58:429–436). Evidence for scavenging by snakes continues to accumulate and scavenging appears to occur fairly frequently among pitvipers and aquatic snakes (DeVault and Krochmal, *op. cit.*).

Just after noon on 24 June 2003 we found an adult *C. viridis* (ca. 900 mm TL) directly below an active Ferruginous Hawk (*Buteo regalis*) nest on the USDA-Forest Service Rita Blanca National Grasslands in Dallam County, Texas. The snake had ingested a large food item. Forced regurgitation revealed the freshly ingested cranial half of a *Cratogeomys castanops* (Yellow-faced Pocket Gopher) whose total length was estimated at 120 mm.

Buteo regalis frequently consume pocket gophers (Giovanni 2004. Prey Partitioning Between Sympatric Grassland Raptors. M.S. Thesis. Texas Tech University, Lubbock. 84 pp.) and prey remains often accumulate at the base of their nests (Marti 1987. *In* Giron Pendelton et al. [eds.] Raptor Management Techniques Manual. Raptor Food Habits Studies, pp. 67–80, National Wildlife Federation, Washington, D.C.). As there was no sign of the posterior half of the food item, it appears that the *C. castanops* was scavenged by the snake after falling from the nest. Raptor nest sites might provide convenient scavenging sites during the birds' breeding season months. DeVault and Krochmal (*op. cit.*) reviewed three prior cases of scavenging in this species, but this is the first incidence of finding scavenged food in the stomach of *Crotalus viridis*.

We thank C. W. Boal, L. Densmore, and T. Devault for assistance and encouragement. Texas Parks and Wildlife Department provided financial support.

DIADOPHIS PUNCTATUS STICTOGENYS (Mississippi Ring-necked Snake). **DIET.** *Diadophis punctatus* are known to feed on plethodontid salamanders (Ernst and Barbour 1989. Snakes of Eastern North America. George Mason Univ. Press, Fairfax, Virginia. 282 pp.) and *D. punctatus stictogenys* are commonly encountered on rocky hillsides in mountainous regions of Arkansas (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville. 421 pp.).

On 10 September 2004 we found a *D. p. stictogenys* (ASUMZ 28733; 217 mm SVL, 44 mm tail length) in direct contact with an adult female *Plethodon albagula* (SVL 69 mm) in a crevice ca. 10 m from the entrance to Spillway Mine, Garland County, Arkansas. A single *P. albagula* egg was found on the floor of the mine below the snake and salamander. The snake was captured (1600 h) and put on ice (1700 h). Necropsy (2100 h) revealed eight eggs (ASUMZ 28734; six fully intact and two ruptured) in the snake's stomach. The six unruptured eggs averaged 5.59 mm in diameter. The snake weighed 4.93 g before necropsy and 3.68 g after the eight eggs (0.94 g total mass) were removed.

Konvalinka and Trauth (2003. Herpetol. Rev. 34:378) report a *Thamnophis sirtalis sirtalis* (Eastern Gartersnake) preying upon an adult *P. albagula* in this mine shaft. Furthermore, *D. p. stictogenys* has been seen in this same mine shaft during previous nesting seasons (three observations) and in one instance was observed preying upon an egg mass (R. R. Jordan, pers. observ.). Female *P. albagula* brood their clutches in crevices and on ledges on the mine shaft walls from August through December (Trauth et

al., *op.cit.*), and female *Plethodon cinereus* are known to abandon eggs when attacked by *D. punctatus* (Bachman 1984. Herpetologica 40:436–443). Thus, although the microclimate of the mine appears to be optimal for *P. albagula* nesting, we hypothesize that the openness of the brooding site increases the risk of predation.

We thank R. R. Jordan, B. A. Wheeler, and the U.S. Forest Service for assistance.

IMANTODES CENCHOA (Chunk-headed Snake, Bejuquilla). **DIET**. The diet of *Imantodes cenchoa* is comprised primarily of *Anolis* lizards and frogs (Henderson and Nickerson 1976. J. Herpetol. 10:205–210; Myers 1982. Amer. Mus. Novitates 2738:1–50; Scott 1983. *In* Janzen [ed.], Costa Rican Natural History, p. 402. The University of Chicago Press, Chicago), but also includes eggs of leaf-breeding anurans such as *Agalychnis* (Scott and Starrett 1974. Bull. So. California Acad. Sci. 73:86–94). On 21 May 2004 an adult female *I. cenchoa* (MHUA 14312, 759 mm SVL, 1093 mm TL, 35 ml volume) was collected from a disturbed primary forest at “El Chaquiral” farm (6º59'00"N, 75º08'05"W; ca. 1700 m elev.) in El Retiro, Anorí municipality, Antioquia Department, Colombia. A female *Anolis mariarum* (61.5 mm SVL, 4 ml volume) was in the snake’s stomach and had been ingested head-first. This is the first report of *Anolis mariarum* in the diet of *I. cenchoa* throughout their distribution in Colombia.

We thank C. Molina, P. C. Mejia-S., L. Bravo, and W. Rios for field assistance. Universidad Nacional de Colombia (Grant DIME-030803682) and Universidad de Antioquia (Grant CODI-IN517CE) provided financial support.

Submitted by **PAUL DAVID GUTIERREZ-C**. (e-mail: pdgutierrez2@yahoo.com) and **JUAN CAMILO ARREDONDO-S.**, Grupo Herpetológico de Antioquia, Instituto de Biología, Universidad de Antioquia, oficina 7-106, A.A. 1226, Medellín, Colombia.

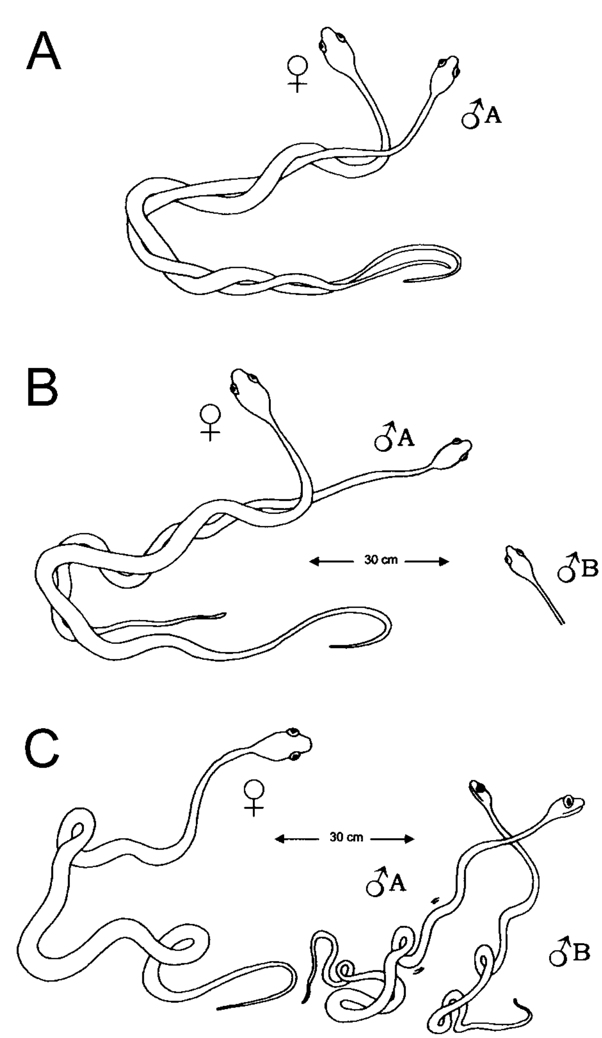

FIG. 1. Mating and fighting in *Imantodes cenchoa*.

IMANTODES CENCHOA (Chunk-headed Snake). **MATING.** Records of mating in Neotropical snakes are scarce, especially for Amazon species (Feio et al. 1999. Herpetol. Rev. 30:99; Cechin and Hartmann 2001. Herpetol. Rev. 32:187). Here, we report mating and fighting by arboreal *Imantodes cenchoa* (Colubridae) in the field. At 1910 h on 8 October 2001 a female (MPEG 20023, 792 mm SVL, 23.2 g) and two males (MPEG 20025, 760 mm SVL, 13.9 g [male A]; MPEG 20024, 742 mm SVL 14 g [male B]) were observed at the top of a tree (3.5 m high) in primary forest at “Estação Científica Ferreira Penna” (1°42'30"S, 51°31'45"W), Pará, Brazil. The female and male A were entwined and obviously mating (Fig. 1A). Male B was 30 cm away on an adjacent branch at the same level. Male B displayed undulating parallel movements and tongue-flicked, but did not touch the mating pair (Fig. 1B). After 20 minutes of observation, the mating pair separated and male B remained distant. Male A approached male B and laterally undulated the anterior portion of his body (but stayed in the same place) for ca. one minute. At this point male A contacted male B, with the anterior portion of his body, forcing male B down and away (Fig. 1C). This sequence was repeated several times before male B retreated. The female remained immobile during the males’ interactions**.** After the observations, the specimens were collected and dissected; all were sexually mature and devoid of prey remains.

We thank Wolmar Wosiacki, Alexandre Bragio Bonaldo, and Renato Vaz for assistance and PNOPG/CNP for financial support.

Submitted by **MARIA CRISTINA DOS SANTOS-COSTA** (e-mail: comboia@uol.com.br) and **ANA LÚCIA DA COSTA PRUDENTE** (e-mail: prudente@museu-goeldi.br), Departamento de Zoologia, Museu Paraense Emilio Goeldi, Avenida Perimetral, 1901, 66040-170, Belém, Pará, Brazil.

LAMPROPELTIS PYROMELANA (Sonoran Mountain Kingsnake). **MAXIMUM LENGTH.** The maximum length reported for *Lampropeltis pyromelana* is 1088 mm TL (Boundy 1995. Bull. Chicago Herpetol. Soc. 30[6]:109–122; Boundy and Balgooyen 1988. Herpetol. Rev. 19:26–27). On 7 July 1995 at

1248 h we captured a male *L. p. pyromelana* at 2037 m in Indian Creek Canyon, Animas Mountains (Hidalgo County, New Mexico, USA) that measured 1114 mm TL (945 mm SVL) and weighed 139 g. The snake was PIT tagged (7F7B0F4840) and released. Between 1994 and 2002 we captured (including recaptures) 55 *L. pyromelana* in the Animas Mountains. Males averaged 627 ± 23 (SD) mm SVL (N = 45, range 274–945) and 741 ± 30 mm TL (N = 40, range 331–1114). Females averaged 635 ± 43 mm SVL (N = 10, range 258–712) and 740 ± 49 mm TL (N = 10, range 313–839).

LEPTOPHIS AHAETULLA MARGINATUS (Southern Green Parrot Snake). **DIET**. *Leptophis ahaetulla marginatus* is a diurnal, arboreal snake known to prey on lizards, birds and their eggs, and hylid frogs (Oliver 1948. Bull. Am. Mus. Nat. Hist. 92:280; Lopez et al. 2003. Herpetol. Rev. 34:68–69). We discovered a Veined Treefrog (*Phrynohyas venulosa*; SVL 66 mm) in the stomach of an adult female *L. a. marginatus* (SVL 875 mm) collected in Foz do Iguaçu (25°33'S, 4°34'W), Paraná, Brazil and deposited in the Instituto Butantan (IB 44678). *Phrynohyas venulosa* exude sticky, toxic secretions that deter predation by some colubrids (*Drymarchon corais*, Leary and Razafindratsita 1998. Amphibia-Reptilia, 19:442–446; *Leptodeira annulata*, Manzanilla et al. 1998. Herpetol. Rev. 29:39–40). However, *P. venulosa* have been recorded in the diet of other colubrids: *Liophis poecilogyrus* (Jorge-da-Silva et al. 2003. Herpetol. Rev. 34:69–70) and *Leptophis mexicanus* (Henderson and Nickerson 1977. J. Herpetol. 11:230–231. This is the first record of predation of *P. venulosa* by *Leptophis ahaetulla*.

We thank F. Franco and R. Balestrin assistance. Coordenação de Aperfeiçoamento de Pessoal de Nível Superior and Conselho Nacional de Desenvolvimento Científico e Tecnológico provided financial support to NRA and MD, respectively.

Ipiranga, 6681, 90619-900, Porto Alegre, Rio Grande do Sul, Brazil.

NAJA MELANOLEUCA (Forest Cobra). **LONGEVITY.** Some species of large snakes are known to be relatively long-lived. Bowler (1975. Longevity of Reptiles and Amphibians in North American Collections. SSAR Herpetol. Circ. 6. 32 pp.) reports over 14 years for *Dendroaspis angusticeps*, 17 years for *Naja naja*, and 29 years for *Naja melanoleuca*; all captive snakes maintained in zoos. In early July 1971, Melbourne Zoo, in Victoria, Australia, received a pair of Forest Cobras (*Naja melanoleuca*) from John Leakey in Kenya, as part of a larger shipment of reptiles. Both snakes were adults (ca. 160 cm TL) and were placed on public exhibit in the Zoo's Reptile House. One of the snakes died 14 days after arrival. The remaining specimen, a female, was anaesthetized on 17 February 2004, for surgical examination of an abdominal mass. An abscess on her left ovary and compromised liver were discovered, and the snake failed to recover from surgery. At the time of her death, she weighed ca. 2200 g and measured 2035 mm SVL (2390 mm TL). She had been in the collection for 32 years, 7 months, and 4 days. Allowing an estimated age of at least two years at the time of her arrival, we conservatively estimate that she exceeded 34 years of age at the time of her death. As far as can be determined, this represents a longevity record for this species and perhaps for elapids overall.

Submitted by **MIKE SWAN** (e-mail: reptiles@zoo.org.au) and **CHRIS BANKS** (e-mail: cbanks@zoo.org.au), Herpetofauna Section, Melbourne Zoo, PO Box 74, Parkville, Victoria 3052, Australia.

NERODIA SIPEDON (Northern Watersnake). **STOMACH CONTENTS**. The diet of *Nerodia sipedon* consists mainly of fishes and amphibians, with a small percentage of reptiles, mammals, birds, and invertebrates (Gibbons and Dorcas 2004. North American Watersnakes: A Natural History. University of Oklahoma Press. 438 pp.). On 2 June 2004 at Dow Lake in Athens, Ohio (USA), a single *N. sipedon* was captured and its stomach contents palpated. This adult female (690 mm SVL, 797 mm TL, 220 g) regurgitated an acorn from a White Oak (*Quercus alba*). No other items were regurgitated.

Submitted by **JACE W. ROBINSON**, Department of Biological Sciences, Northern Illinois University, DeKalb, Illinois 60115, USA (e-mail: z052078@wpo.cso.niu.edu).

OXYBELIS FULGIDUS (Green Vine Snake). **DIET**. *Oxybelis fulgidus* is diurnal and primarily arboreal when active (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150) and preys primarily on small lizards (*Ameiva*, *Anolis*, and *Norops*) and birds (*Pipra*, *Traupis*, and *Volatinia*; Leenders and Colwell 2003. Herpetol. Rev. 34:152; Martins and Oliveira, *op. cit*.). Although *O. fulgidus* is primarily an ambush predator (Henderson and Binder 1980. Milwaukee Publ. Mus. Contrib. Biol. Geol. 37:1–38), it occasionally actively forages for prey (Martins and Oliveira, *op. cit*.; Leenders and Colwell, *op. cit.*). Here, we describe the behavior of an *O. fulgidus* preying upon a bird. At ca. 1445 h on 8 May 2004, at Parque da Araras (03º03'0.81"S; 60º17'0.93"W), Manaus, Amazonas, Brazil, we watched an adult *O. fulgidus* (ca. 1500 mm TL) capture and consume an *Elaenia* sp. (Tyrannidae: Passeriformes). The snake was ca. 7 m up in a tree when the bird perched near it. The snake seized the bird in the left scapular region and held it for ca. 8 minutes, at which point it had become immobilized by the snake's Duvernoy's gland secretions. Ingestion lasted ca. 20 minutes.

PITUOPHIS CATENIFER SAYI (Bullsnake). **PREDATION**. Although Coyotes (*Canis latrans*) have been mentioned as a predator of broadly sympatric *Pituophis catenifer* (e.g., Ernst and Ernst. 2003. Snakes of the United States and Canada. Smithsonian Books, Washington. 668 pp.; Koch and Peterson. 1995. Amphibians and Reptiles of the Yellowstone and Grand Teton National Parks. University of Utah Press, Salt Lake City. 188 pp.), few definitive reports of such predation exist in the literature. Furthermore, these few reports are dated and concentrated in the western United States. Fitch (1949. Am. Midl. Nat. 41:513–579) published detailed data regarding coyotes preying upon *P. catenifer* in California. Johnson (1936. J. Mammal. 17:169–170) reported witnessing a coyote kill and consume what he believed was a *P. catenifer* in Arizona. However, according to his report, he was never closer than within 200 ft of the coyote or the snake, did not report a scientific name for the snake, and was never able to inspect the carcass of the snake for positive specific or subspecific identification. Here we report evidence of *C. latrans* predation on *P. catenifer* and provide information suggesting that predation might occur at relatively high frequency.

During the summer of 2004 we radio-tracked 23 *P. catenifer sayi* in the Lower Wisconsin River Valley, Sauk County, Wisconsin (USA). On 2 July 2004 we located a radio-tagged female *P. catenifer sayi* (1195 mm SVL, 1010 g) in a *C. latrans* den. After a week of no movement, we believed the snake might have been consumed by a *C. latrans*. On 15 July 2004 we searched the area surrounding the den entrance and found a pile of *C. latrans* scat that appeared to have been passed several days earlier. This scat contained many small rodent bones and a large number of snake ventral scales. The size and shape of these scales suggested they were those of *P. catenifer* and not one of the other three snakes known from this study site (*Coluber constrictor*, *Heterodon platirhinos*, *Lampropeltis triangulum*).

Furthermore, between 16 May and 18 August 2004, six additional radio-tracked adult (4M:2F) *P. catenifer* were killed and eaten by carnivorous mammals in lowland oak savannah habitat immediately adjacent to open sand prairie and bluffs. In two instances, the transmitters were found within a *C. latrans* den; in two other instances the chewed carcass of the snake (with transmitter) was discovered; and in the remaining two instances, the transmitter (with evidence of carnivorous mammal teeth marks) was found with no carcass. Although all six of these observations are consistent with predation by *C. latrans*, in only one case was scat containing snake scales found adjacent to the coyote den entrance. Although we also radio-tracked 21 *P. catenifer* during the spring and summer of the preceding year (2003), none was preyed upon.

PROTOBOTHROPS JERDONII XANTHOMELAS (Chinese Mountain Pitviper). **REPRODUCTION.** Few data exist in herpetological literature on the reproductive biology of any of the three subspecies of *Protobothrops jerdonii*. Pope (1935. The Reptiles of China. Amer. Mus. Nat. Hist., New York. 604 pp.) summarized data on litter size from females originating from Szechwan Province, China. Smith (1981. The Fauna of British India, Ceylon, and Burma. Reptilia and Amphibia, Vol. III, Serpentes. Today and Tomorrow's Printers and Publishers, New Delhi. 583 pp.) noted that young from Burma are "7 to 8 inches" long. Here I report a litter born to an adult female *Protobothrops jerdonii xanthomelas* (710 mm SVL, 135 mm TL, and 98.8 g after parturition) collected from the wild in Szechwan Province, China on 16 June 2004. On 3 August 2004 she gave birth to six neonates in captivity. Neonates had a mean SVL of 209.5 mm ± 5.4 SD (range = 199–219 mm), a mean TL of 42.3 mm ± 4.3 SD (range = 37–49 mm), and a mean mass of 6.3 g ± 0.45 SD (range = 5.85–6.98 g).

Submitted by **R. MICHAEL BURGER**, P.O. Box 4099, Dallas, Texas 75208, USA (e-mail: mvburger@dctexas.net).

PSEUDOERYX PLICATILIS PLICATILIS (Eel Snake)**. REPRODUCTION**. Little is known about the reproductive biology of *Pseudoeryx plicatilis*, and what few isolated anecdotal observations exist pertain to *P. plicatilis mimeticus* (Cunha and Nascimento 1981. Bol. Mus. Paraense Emílio Goeldi, nov. sér: Zool. 109:1–20). On 7 January 2002, D. Amaral collected an adult female *P. plicatilis plicatilis* (1370 mm SVL, 1577 mm TL) and her clutch of 49 eggs from Santarém (2°26'S, 54°42'W) on the right bank of the River Tapajós, Pará State, Brazil. The female and her freshly laid eggs (covered with viscous liquid when found) were found inside a drainage pipe and donated to our lab. The eggs contained fully developed juveniles. Forty-eight of 49 eggs hatched between 7 and 10 January 2002; the remaining egg contained a fully developed snake that failed to hatch. Female hatchlings (N = 26) averaged 186 mm SVL (171–200, SD = 8.8), 222 mm TL (202–236, SD = 7.7), and 8.0 g (5.6–9.3, 0.9). Male hatchlings (N = 22) averaged 180 mm SVL (168–187, SD = 4.8), 224 mm TL (207–234, SD = 6.3), and 7.8 g (5.5–10.4, SD = 0.9). The juveniles were kept in captivity until they had shed, which ranged from 11 to 18 days after hatching. The specimens are deposited in the scientific collection of the Laboratório de Pesquizas Zoologicas (LPZ) of the Faculdades Integradas do Tapajós (FIT).

PSEUSTES POECILONOTUS and ***PSEUSTES SHROPSHIREI*** (Puffing Snakes). **DIET**. *Pseustes poecilonotus* is known to prey on birds (Falconidae, Emberizidae), bird eggs

(Cracidae), and occasionally on lizards and small mammals (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150). There is no published information regarding *Pseustes shropshirei* diet. On 9 January 1991 a specimen of *P. poecilonotus* (Universidad San Francisco de Quito y Fundación Herpetológica Orcés; FHGO-USFQ 0192) was collected on the Río Payamino at Pozo Gacela, Province of Napo, Ecuador, that contained one adult beetle (Coleoptera: Scarabeidae), one moth (Lepidoptera), parts of a grasshopper (Orthoptera), parts of a bug (Hemiptera), and two legs of a woodpecker (Piciformes: Picidae). On 25 March 1994 a specimen of *P. shropshirei* (FHGO-USFQ 0892) collected at Piñas, Buenventura, Province of El Oro, Ecuador, contained a capsule of seeds from an undetermined plant (ca. 2 cm in diameter) and two white brittle-shelled eggs (ca. 3 cm in diameter) with partially developed avian embryos.

I thank Jean-Marc Touzet, Ana María Velasco, Daniel Proaño, María Olga Borja, Ma. Elena, and Laura Heredia for assistance.

RAMPHOTYPHLOPS MULTILINEATUS (Striped Blind Snake). **BEHAVIOR**. Scolecophidians typically are regarded as fossorial. However, recent reviews (Das and Wallach 1998. Herpetol. Rev. 29:15–16; Gaulke 1995. Asiatic Herpetol. Res. 6:45–48) report both literature and novel records of arboreality in scolecophidians. Most of these records involve observations of snakes 0.5–5 m up the trunk of trees or climbing in limbs or palm fronds. However, Taylor (1922. The Snakes of the Philippine Islands. Bureau of Printing, Manila. 312 pp.) reported the occurrence of *Ramphotyphlops cumingii* (in his description of *Typhlops dendrophis*) in the root masses of aerial ferns (*Asplenium* sp.) from "high forest trees" where he suggested they feed on ant larvae and centipedes. We report here on climbing behavior in a specimen of *Ramphotyphlops multilineatus* (verified by V. Wallach) from the Crater Mountain Biological Research Station at Wara Sera, Chimbu Province, Papua New Guinea (6°43'S, 145°05'E). These snakes and their close relatives often prey upon ant pupae, larvae, and adults as well as termites (Shine and Webb 1990. J. Herpetol. 24:357–363; Webb and Shine 1993.Copeia 1993:762–770; Webb et al. 2001. J. Zool. London 250:321–327). This specimen (BSFS 11672, National Museum and Art Gallery of Papua New Guinea in Port Moresby) was collected at a height of 8 m from an interior chamber of a carpenter ant nest at the base of an epiphytic staghorn fern growing on the side of a large tree.

SALVADORA MEXICANA (Mexican Patch-nosed Snake). **REPRODUCTION.** *Salvadora mexicana* is known to be oviparous (García and Ceballos 1994. Field Guide to the Reptiles and Amphibians of the Jalisco Coast, México. Fundación Ecológica de Cuixmala, A.C., Centro de Ecología, UNAM, México, D.F.), but to my knowledge there is no other published information on its reproduction. The purpose of this note is to provide additional information on the reproductive cycle of *S. mexicana* based on histological examination of gonads removed from museum specimens.

I examined three female (703 ± 109 mm SVL, range 596–813 mm) and four male (747 ± 44 mm SVL, range 710–805 mm) *S. mexicana* from the herpetology collections of the Natural History Museum of Los Angeles County (LACM) and the University of Arizona (UAZ). Histological procedures follow Goldberg (2004. Herpetol. Rev. 35:59). Spermiogenesis was in progress and the vas deferens contained sperm in all four males examined (LACM 136964, June, 716 mm SVL; LACM 25930, July, 756 mm SVL; LACM 75063, July, 805 mm SVL; LACM 58144, September, 710 mm SVL) indicating a prolonged period of sperm production. A female (LACM 2691; 700 mm SVL) collected in June from Jalisco contained 4 oviductal eggs. A female (LACM 74033; 813 mm SVL) collected in July from Guerrero contained three enlarged follicles (mean length = 27.4 mm ± 4.4 SD). Another female (UAZ 26331; 596 mm SVL) captured in August from Colima was undergoing yolk deposition (= secondary vitellogenesis *sensu* Aldridge 1979. Herpetologica 35:256–161), suggesting that some females might produce a second clutch of eggs the same year. These are the first clutches reported for *S. mexicana.*

I thank D. A. Kizirian (LACM) and G. L. Bradley (UAZ) for permission to examine specimens.

SISTRURUS CATENATUS (Eastern Massasauga). **MATING ACTIVITY**. Narrative reports of reproductive behaviors by free-ranging snakes are infrequent, yet accretion of such observations is essential to characterizing mating systems and reproductive phenology. Here we describe reproductive behaviors observed during the course of a radio-telemetric study of adult *Sistrurus catenatus* conducted during summer and fall of 1993 in Will County, Illinois (Wilson and Mauger 1999. *In* B. Johnson and M. Wright [eds.], Second International Symposium and Workshop on the Conservation of the Eastern Massasauga Rattlesnake, *Sistrurus catenatus catenatus*, pp. 110–134, Toronto Zoo, Toronto, Ontario).

On 27 July at 2000 h we found an unmarked male coiled on top of a radio-tagged female (10L; 570 mm SVL), but the male escaped into tall dense vegetation. On 29 July at 2000 h we observed a male (possibly the same male) coiled on top of 10L. The male (8L9L; 665 mm SVL) was removed and surgically implanted with a radio-transmitter. On 2 August at 1900 h, another male (7L; 600 mm SVL) found on top of 10L was captured. On 07 August we released 7L next to 10L, although he moved away and subsequently was never found with 10L. During the time 7L was removed, no other males were found with 10L. Male 8L9L was released on 07 August at his last point of capture but did not immediately approach 10L, even though the snakes were close. On 12 August 8L9L was again coiled on top of 10L and for the next 19

days remained either coiled on top of, next to, or in close proximity (< 2m) to her. On 17 August 8L9L and 10L were coiled together with the posterior third of their bodies intertwined. We could not determine if the cloacae were in apposition, nor did we observe any other behaviors characteristic of courtship or copulation. By 31 August 8L9L was coiled alone 15 m from 10L and no subsequent interactions between the pair were observed. On 17 September male 8L9L was found coiled atop another female (8R; 550 mm SVL). After capturing and marking 8R, we released her at 8L9L's location on 18 September and she moved away and 8L9L did not follow. Subsequent observations were not possible due to failure of 8L9L's transmitter on 20 September.

After a prolonged period of accompaniment by 8L9L, 10L made frequent movements and on 9 September at 1350 h was found copulating with another male (3L, 590 mm SVL). At 1415 h they separated, possibly because of our presence. Although we tracked snakes on a daily basis as late as early November, no further reproductive behavior was observed by 10L after 9 September. Our third snake, male 6R (555 mm SVL), showed no reproductive behavior throughout the study.

Multiple observations of males coiling on top of females and the prolonged accompaniment exhibited by 8L9L are behaviors consistent with female defense polygyny. However, because we did not observe any male-male interactions, it is unclear if these behaviors constitute mate-guarding. Male *S. catenatus* have also been observed coiled on top of females during the mating season at Lake Carlyle, Illinois (M. J. Dreslik and B. C. Jellen, pers. comm.). A similar behavior (termed "stacking") has been observed in *Crotalus atrox* from central Arizona (J. O'Leile, pers. comm.). Although we only observed female 10L copulating with male 3L, her coiling with two other males, including the prolonged accompaniment by male 8L9L, suggests the potential for multiple mating by females.

We thank T. G. Anton, M. J. Dreslik, C. H. Ernst, B. C. Jellen, and P. J. Wilson for assistance and advice.

WILSON**, Department of Biological and Environmental Sciences, #2653, 215 Holt Hall, University of Tennessee at Chattanooga, 615 McCallie Avenue, Chattanooga, Tennessee 37403, USA.

SPILOTES PULLATUS (Tiger Ratsnake). **REPRODUCTION.** *Spilotes pullatus* is a diurnal, semi-arboreal colubrine snake (Marques and Sazima 2004. *In* Marques and Duleba [eds.], Estação Ecológica Juréia-Itatins: Ambiente Físico, Flora e Fauna, pp. 254–274. Holos, Ribeirão Preto, S.P.), that is widely distributed in Brazil (Peters and Orejas-Miranda 1986. Catalogue of Neotropical Squamata. Smithsonian Institution Press, Washington, D.C. 284 pp.).

On 13 November 2003 a female *S. pullatus* (IB 69849: 1650 mm SVL, 210 mm tail length, 920 g after oviposition), collected in Pedro de Toledo (24°16'29"S, 47°13'58"W), São Paulo, southeastern Brazil, was brought to Instituto Butantan (IB). On the same day it laid 12 eggs, averaging 48.2 mm in length (range = 39.8–62.0 mm) and 29.6 mm in width (range = 25.5–34.0 mm). Clutch size reported here exceeds that previously reported for *S. pullatus* (5–10 eggs; Marques and Sazima, *op. cit.*). Relative clutch mass (RCM) was 0.36, which is similar to that reported for other oviparous snakes (Seigel and Fitch 1984. Oecologia 61:293–301). During incubation, ten eggs became infected by fungi and did not hatch. One newborn (male, 350 mm SVL, 115 mm tail length, 15 g) hatched on 8 March 2004. The other egg was dissected on 13 March 2004 and a dead but fully developed neonate was discovered inside (IB 71360; female, 364 mm SVL, 115 mm tail length, 19 g). Marques and Sazima (*op. cit.*) suggested that reproduction in *S. pullatus* is seasonal, although this inference was based on a limited number of preserved specimens (three vitellogenic individuals from July to October, and one with oviductal eggs in November), and one observation of oviposition in October and hatching in January. Our observation is consistent with the notion of seasonal reproduction, with oviposition early in the rainy season and hatching near the end of the rainy season.

We thank M. da Graça Salomão and O. A. V. Marques for assistance and suggestions. FUNDAP and FAPESP provided financial assistance.

STORERIA STORERIOIDES (Mexican Brown Snake). **REPRODUCTION.** Relatively little has been published regarding reproduction in *Storeria storerioides*. Guillette (1981. Herpetologica 37:11–15) reported that it is viviparous with mating in the fall. Ramírez-Bautista et al. (1995. J. Herpetol. 26:12–13) reported a mean litter size of 5.4 (range 3–10, N = 5) in *S. storerioides* from the state of México. On 27 April 2004 at 1300 h a female *S. storerioides* (Colección Herpetologica, Instituto de Investigaciones sobre los Recursos Naturales, Universidad Michoacana; INIRENA 483) measuring 244 mm SVL (52 mm TL) was found among pine-oak leaf litter 5 km W of Uruapán, Michoacán, México (19°22'4"N, 102°04'6"W, 1660 m elev.). On 23 June 2004 she gave birth in captivity to three neonates, after which she weighed 5 g. The neonates measured (mean ± SD) 69.3 ± 16.2 mm SVL (range: 59–88 mm SVL), 14.0 ± 2.6 mm TL (12–17 mm TL), and 0.1 ± 0.05 g (0.1–0.2 g).

I thank José Magaña for collecting the snake and Coordinación de Investigación Científica, Universidad Michoacana for assistance.

THAMNOPHIS VALIDUS CELAENO (Baja California Gartersnake). **MORTALITY**. The most common macrobiological source of mortality for gartersnakes is predation by various verte-

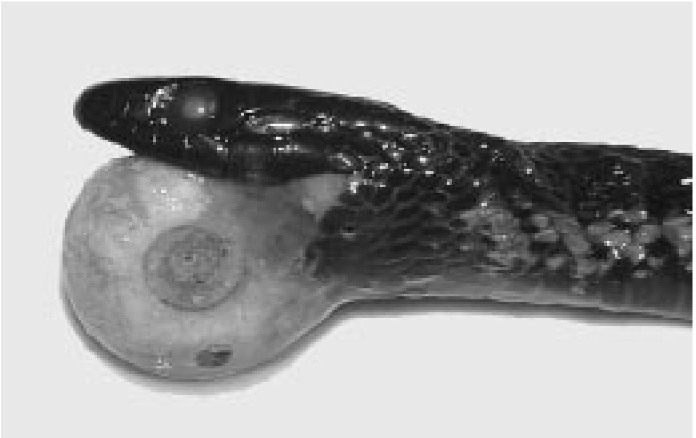

FIG. 1. Subadult *Thamnophis validus celaeno* (UABC 1016) with lower mandibles lodged in the aperture of a freshwater snail (Planorbidae: Planorbella subcrenatum).

brates (Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. Univ. Oklahoma Press, Norman. 332 pp.). To our knowledge, mortality caused by invertebrates has not been reported (but see Schwendiman 2004. Herpetol. Rev. 35:73). Here we describe an apparent accidental case of subadult mortality caused by an aquatic gastropod.

On 02 April 2003 at ca. 1700 h we collected a subadult *Thamnophis validus celaeno* (UABC 1016; 303 mm SVL) from Arroyo Boca de la Sierra in the Sierra la Laguna, ca. 5 km NW of Miraflores (23°23.118'N, 109°49.022'W), Baja California Sur, México. The specimen was found dead on a sandy bank near a pool of water at the base of a concrete dam. The lower mandibles were firmly lodged within the aperture of an aquatic snail's (Planorbidae: *Planorbella subcrenatum*) shell; thus preventing the snake from closing its mouth (Fig. 1). These snails were abundant in the shallows of this and surrounding pools. The diet of *T. v. celaeno*, specifically for populations from the Sierra de la Laguna, is described as consisting entirely of larval and adult anurans and small fish (de Queiroz et al. 2001. Copeia 2001:1034–1042). However, given that snails/slugs have been reported in the diets of other *Thamnophis* species (e.g., *T. elegans*, *T. ordinoides*, *T. sirtalis*; Rossman et al. 1996, *op. cit.*), we examined the stomach contents of UABC 1016 along with two other specimens (UABC 1071, 1316) collected the same day. No prey items were discovered in all three specimens. Nonetheless, we presume that this event represents an accidental occurrence of mortality during a feeding attempt, yet it is possible that the snake did not target this specific prey item. It has been suggested that *T. validus* are less adapted to visual underwater feeding than are other strongly aquatic garter snakes and instead rely more on a tactile open-mouth foraging method (Conant 1969. Bull. Am. Mus. Nat. 142:1–140; de Queiroz 2003. Ethology 109:369–384). It is presumed that the individual died from starvation and/or exhaustion after trying to remove the snail from its mandibles.

We thank Kathryn Perez at the University of Alabama for helping identify the snail.

TRIMORPHODON BISCUTATUS (Lyre Snake). **DIET.** On 9 April 2003 at 1950 h we observed an adult *Trimorphodon biscutatus* hunting Gray Sac-winged Bats (*Balantiopteryx plicata*) as they exited a small cave known as the Coat of Tláloc located in Area Natural Protegica Sierra Montenegro, Morelos, México (18°30'44.3"N, 99°00'39.8"W, 1104 m elev.). Our observation adds to a growing body of literature that suggests *T. biscutatus* feeds fairly frequently on colonial bats (Krutzsch 1944. J. Mammal. 25:410–411; Sánchez-Hernández and Ramírez-Bautista 1992. Herpetol. Rev. 23:121; Stager 1942. J. Mammal. 23:92).

We thank M. Barrios Damián for assistance.

Submitted by **ROSMANDI LARA LÓPEZ** (e-mail: rlara@cib.uaem.mx), **ALFREDO CHÁVEZ MARTÍNEZ, RUBÉN CASTRO FRANCO** (e-mail: castro@cib.uaem.mx), **ALEJANDRO GARCÍA FLORES,** and **SANDRA DENNISE BARRETO SÁNCHEZ**, Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Morelos. TRIMORPHODON TAU (Mexican Lyre Snake). **REPRODUCTION**. Information on reproduction in *Trimorphodon tau* consists of one report of a clutch of seven eggs from a female collected 18 July (McDiarmid and Scott. 1970. Contrib. Sci. 179, Los Angeles County Mus. 43 pp.). Here I report additional information on *T. tau* reproduction. Fifteen males (mean SVL = 548 ± 48 mm SD, range = 477–650 mm) and eight females (705 ± 108 mm SVL, range = 545–870 mm) were examined from the herpetology collections of Arizona State University (ASU), the Field Museum of Natural History (FMNH), Natural History Museum of Los Angeles County (LACM) and the University of Arizona (UAZ). Snakes were collected 1953–1977. Histological procedures follow Goldberg (2004. Herpetol. Rev. 35:59). One August female (LACM 122906, 630 mm SVL) contained 8 enlarged follicles (> 8 mm length) that likely would have ovulated and represent the second published clutch for *T. tau.* One February female (FMNH 71531, 688 mm SVL), three July females (LACM 53024, 545 mm SVL; LACM 125589, 870 mm SVL; LACM 103390, 740 mm SVL), two August females (LACM 122904, 730 mm; UAZ 36377, 823 mm) and one December female (LACM 53206, 617 mm) were not undergoing yolk deposition (= secondary vitellogenesis, *sensu* Aldridge 1979. Herpetologica 35:256–261). All males were undergoing spermiogenesis (= sperm formation). This included one February male (FMNH 71532, 480 mm SVL), one April male (LACM 9157, 561 mm SVL), four July males (ASU 6377, 590 mm SVL; ASU 6684, 562 mm SVL; LACM 127811, 552 mm SVL; LACM 125587, 565 mm SVL), six August males (ASU 6651, 650 mm SVL; ASU 6663, 573 mm SVL; ASU 6712, 495 mm SVL; LACM 7109, 477 mm SVL; LACM 7110, 533 mm SVL; LACM 7111, 572 mm SVL), two September males (UAZ 27023, 480 mm SVL; UAZ 45492, 580 mm SVL) and one November male (LACM 9509, 562 mm SVL). The presence of males undergoing spermiogenesis in winter, spring, summer, and autumn

suggests *T. tau* has a prolonged testicular cycle similar to its congener *Trimorphodon biscutatus*. Males of *T. biscutatus* from Arizona were undergoing spermiogenesis in January and March–October (Goldberg 1995. Southwest. Nat. 40:334–335).

I thank G. Bradley (UAZ), A. Holycross (ASU), D. Kizirian (LACM), and A. Resetar (FMNH) for permission to examine specimens.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

TROPIDOPHIS PILSBRYI (NCN). **SIZE RECORD.** On 19 September 1980 Orlando H. Garrido and José F. Milera collected a female *Tropidophis pilsbryi* from the grounds of the Asunción Hotel, Maisí, Guantánamo Province, Cuba. This specimen (CZACC 4.12076; Colecciones Zoológicas del Instituto de Ecología y Sistemática, Havana City Province, Cuba) measures 371 mm snout–vent length and 47 mm tail length. A second female *T. pilsbryi* (CTR 27; "Charles T. Ramsden" Collection, deposited at the Instituto de Ecología y Sistemática) collected from Babiney, Hoyo del Río Guaso, Monte Líbano, Guantánamo Province, Cuba by Charles T. Ramsden on 17 February 1931, was erroneously identified as *Tropidophis maculatus* by the collector and later by Orlando H. Garrido and measures 307 mm snout–vent length and 41 mm tail length. The first specimen has 175 ventrals and 36 subcaudals, while the second specimen has 166 ventrals and 28 subcaudals. The previously reported maximum length for this species is 295 mm SVL (Hedges and Garrido 2002. J. Herpetol. 36:157–161). These specimens present external pelvic spurs and also extend the previously reported range of variation in both ventral and subcaudal counts from 160–169 to 160–175 ventrals and from 29–35 to 28–36 subcaudals (Hedges and Garrido 2002, *op. cit.*).

We thank Elier Fonseca and Lourdes Rodríguez Schettino for suggestions on the manuscript.

Submitted by **MICHEL DOMÍNGUEZ** (e-mail: micdom2002@yahoo.es) and **LUIS V. MORENO**, División de Colecciones Zoológicas, Instituto de Ecología y Sistemática, Carretera de Varona km 3, Capdevila, Boyeros, A.P. 8029, C.P. 10800, Ciudad de La Habana, Cuba.

TROPIDOPHIS WRIGHTI (NCN). **REPRODUCTION**. *Tropidophis wrighti* is endemic to Cuba and ranges from Northern Sancti Spiritus Province to Guantanamo Province (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History. Florida Univ. Press, Gainesville. 720 pp.). On October 2001 a gravid female *Tropidophis wrighti* (335.5 mm total length) was discovered under a stone in an ecotone between pine forest and xeromorphic sub-thorny thicket on the Pinares de Mayari Plateau, in Sierra de Nipe (645 m elev.), Holguín, Cuba. This female contained a 154.0 mm (TL) neonate. Both specimens are deposited in the herpetological collection at the Institute of Ecology and Systematics (CZACC 4.9479-480). To the best of our knowledge, the only other record of clutch size or neonatal morphometrics in the genus *Tropidophis* is Petzold's (1969. Salamandra 5:124–140) report of a neonate *T. semicintus* (160 mm and 1.5 g, respectively).

Submitted by **ALEJANDRO FERNÁNDEZ VELÁZQUEZ**, Centro de Investigaciones y Servicios Ambientales y Tecnológicos, Grupo de Recursos Naturales, Holguín, Cuba (e-mail: ale@cisat.holguin.inf.cu); and **ROBERTO ALONSO,** Divisón de Zoología de Vertebrados, Instituto de Ecología y Sistemática, Carretera de Varona km 3, Capdevila, Boyeros, AP 8029, CP 10800, Ciudad de la Habana, Cuba (e-mail: zoologia.es@ama.cu).

GEOGRAPHIC DISTRIBUTION

Instructions for contributors to Geographic Distribution appear in Volume 36, Number 1 (March 2005). Please note that the responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extension reports unless a thorough literature review has been completed.

CAUDATA

AMBYSTOMA MACULATUM (Spotted Salamander). USA: NORTH CAROLINA: Henderson Co: 5.6 km SW Tuxedo. 28 March 1997. David A. Pike. Verified by Jeffrey C. Beane. North Carolina State Museum (NCSM slide DAP 97-385). First vouchered county specimen (NCSM files). Egg masses were also observed in a breeding pond at the same locality on 29 March 1997.

Submitted by **DAVID A. PIKE**, Glatting Jackson, Inc., Environmental Services Group, Orlando, Florida 32801,USA (e-mail: dapike22@hotmail.com); **DAVID G. COOPER**, North Carolina State Museum of Natural Sciences, 11 West Jones Street, Raleigh, North Carolina 27601, USA; and **DALE A. JACKAN**, 311 Merrick Road, Tryon, North Carolina 28782, USA.

ENSATINA ESCHSCHOLTZII KLAUBERI (Large-blotched Ensatina). MEXICO: BAJA CALIFORNIA: Sierra de Juárez, ca. 19 km airline S of Laguna Hanson. Two specimens were recorded. The first specimen was seen at Rancho Las Cuevitas, 0.7 km E of, 31˚53.021'N, 115˚55.780'W, 1540 m elev., in pine-oak forest. 8 May 2005. C. D. Heim, B. Alexander. Museum of Vertebrate Zoology (MVZ 249145, photo voucher). The second specimen was located at Rancho Baja Largo del Sur, 2.0 km NW of, 31˚52.304'N, 115˚55.850'W, 1602 m elev., in pine-oak forest, on NE-facing slope, during a rainy day. 29 July 2005. J. H. Valdez-Villavicencio, B. D. Hollingsworth, T. J. Devitt, C. R. Mahrdt, J. A. Soto-Centeno. Universidad Autónoma de Baja California (UABC 1433). Verified by D. B. Wake. First records from the Sierra de Juárez and represents an isolated population that fills a 240 km distributional gap between the Sierra San Pedro Mártir, B.C. (Mahrdt et al. 1998. Herpetol. Nat. Hist. 6[1]:73–76; MVZ 229220–1) and Alpine, San Diego Co., California (Stebbins 1949. Univ. California Publ. Zool. 48[6]:377–526; SDSNH 32525–7). The two Sierra de Juárez localities are 1.5 km from each other in a north–south direction. Unconfirmed reports also exist from the vicinity of Laguna Hanson in the Sierra de Juárez (see overview in Grismer 2002. Amphib-

ians and Reptiles of Baja California Including its Pacific Islands and the Islands in the Sea of Cortés. Univ. California Press, Berkeley and Los Angeles, California. p. 61).

A.A 384 Pasto, Colombia (e-mail: ffelcacolombia@yahoo.com).

BARYCHOLOS PULCHER (NCN). ECUADOR: PROVINCIA DE AZUAY: Tamarindo (79°33'W, 02°47'S, 400 m). 04 August 1996. J.-M. Touzet et al. Universidad San Francisco de Quito & Fund. Herpetológica Orcés, Quito (FHGO-USFQ 623, 748, collected in the leaf litter). Verified by W. Ron Heyer. This endemic frog is known from western lowlands of Ecuador along the transition zone between rainforest and dry seasonal forest from 30 to 600 m; with previous records in the provinces of Esmeraldas, Manabí, Guayas, Los Ríos, and Pichincha (Heyer 1969. Contrib. Sci. Los Angeles Co. Mus. Nat. Hist. 155:1–14). First province record, extends its range ca. 70 km NE from the nearest known locality (7 km SE Buenavista, province of Oro; Heyer, *op. cit*.).

Submitted by **DIEGO F. CISNEROS-HEREDIA**, College of Biological and Environmental Sciences, Universidad San Francisco de Quito, Ave. Interoceánica y calle Diego de Robles, Campus Cumbayá, Edif. Maxwell. Casilla Postal 17-12-841, Quito, Ecuador; e-mail: diegofrancisco_cisneros@yahoo.com.

BUFO GUTTATUS (Spotted Toad, Smooth-sided Toad): ECUADOR: PROVINCIA SUCUMBÍOS, Reserva de Producción Faunística Cuyabeno: Puerto Bolívar, (00°05'19"S, 76°08'31"W, 240 m elev.) 05, 07 and 14 August 2003. M. Guerrero, P.A.Menéndez and M.R.Bustamante. Museo de Zoología, Pontificia Universidad Católica del Ecuador, Quito, Ecuador (QCAZ 26013–4, 26414). 4 km N of Tarapoa (00°07'24"S, 76°20'24"W, 230 m elev.). 20 July 2000. D. F. Cisneros Heredia, M. Brandt, A. León, and C. Ponce. Laboratorio de Anfibios y Reptiles FHGO-USFQ Universidad San Francisco de Quito (DFCH-USFQ 0715). PROVINCIA ORELLANA: Parque Nacional Yasuní: Tiputini Biodiversity Station (00°37'05"S, 76°10'19"W, 215 m). 23 November 1996. D. Romo. (QCAZ 10211). 11 August and 23 November 1999. D. F. Cisneros Heredia and K. Swing. (DFCH-USFQ 0270, DFCH-USFQ 0710). Estación Científica Yasuní (00°40'16.7"S, 77°24'01.8"W, 250 m). 20 February 2002. I. Tapia and G. Carotti. (QCAZ 19247). All verified by L. A. Coloma. Frost (1985. Amphibian Species of the World. A Taxonomic and Geographical Reference. Allen Press and the Association of Systematics Collections, Lawrence, Kansas; and 2002. Amphibian Species of the World. [on line]. V2.21 [15 July 2002]). Museum of Natural History. New York, http://research.amnh.org/herpetology/amphibia/index.html) reports this species from Colombia, Guyanas, Venezuela, Amazonian and central Brazil and Ecuador, although no published records with associated voucher specimens were available for Ecuador. Because no vouchers existed, Coloma and Quiguango-Ubillús (2000–2004. Anfibios de Ecuador: Lista de Especies y Distribución Altitudinal [online]. Ver. 1.3 [2 April 2001]). Museo de Zoología, Pontificia Universidad Católica del Ecuador. Quito, Ecuador. « http://www.puce.edu.ec/zoologia/vertebrados/amphibiawebec/index.html) did not include *B. guttatus* in the list of Ecuadorian amphibians. These specimens represent the first vouchered records from Ecuador. Estación Científica Yasuní extends the range of the species ca. 990 km to the west from the nearest known locality "east of Departamento de Vichada" in Colombian Amazonia (Ruíz-Carranza et al. 1996. Rev. Acad. Colomb. Cienc. 20[77]:366–415).

Submitted by **MARTÍN R. BUSTAMANTE** and **PABLO A. MENÉNDEZ**, Museo de Zoología, Centro de Biodiversidad y Ambiente, Escuela de Biología, Pontificia Universidad Católica del Ecuador, Av. 12 de Octubre y Roca, Aptdo. 17-01-2184, Quito, Ecuador (e-mail: mrbustamante@puce.edu.ec); and **DIEGO F. CISNEROS-HEREDIA**, Laboratorio de Anfibios y Reptiles FHGO-USFQ, Universidad San Francisco de Quito, Av. Interoceánica y calle Diego de Robles, edif. Newton Plaza, of. BUFO MARINUS (Cane Toad). LESSER ANTILLES: ST. VINCENT: The Grenadines: Mustique Island, northern part of island by pond at Buttercup House on eastern side of the north end of airstrip, at about sea level. 9 February 2004. M. R. Paice. MPM - P718 (photograph). Verified by Robert W. Henderson. First record

for Mustique Island, although it has been recorded from St. Vincent in general (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History. Univ. Florida Press, Gainesville, Florida, xvi + 720 pp). This exotic species, first noticed by islanders in early 2003, was likely an accidental introduction with building material. At least four other individuals were observed near the airstrip, so a breeding colony has probably been established on the island.

Submitted by **MICHAEL R. PAICE**, 8D Rochdale Way, London SE8 4LY, UK; e-mail: mrpaice@yahoo.co.uk.

ELACHISTOCLEIS PIAUIENSIS (Piaui Oval Frog): BRAZIL: CEARÁ: MUNICIPALITY OF MOMBAÇA: Fazenda Minador (05º40'08.25"S, 39º38'20.43"W, elev. 401 m). 15 July 2004. E. Maranhão dos Santos, P. Thieres Pinto de Brito, F. Oliveira Amorim, and I. Joventino Roberto. Verified by M. Trefault Rodrigues and E. M. Xavier Freire. Coleção Herpetologica do Departamento de Botânica, Ecologia e Zoologia, Instituto de Biociência, Universidade Federal do Rio Grande do Norte (CHBEZ 1028). Adult specimen (SVL 21.4 mm). Previously known only from the type locality: Picos, State of Piauí, in northeastern Brazil (Caramaschi and Jim 1983. Herpetologica 39[4]:390–394). First state record, extends the known distribution 258 km SW.

PHYLLOMEDUSA SAUVAGII. ARGENTINA: SAN JUAN: Departamento Valle Fértil: 250 km San Juan city on Astica, Ruta Provincial N° 510 (30°59'S, 67°22'W), January 2004. M. Jordan and E. Herrera. Herpetological Collection, Instituto y Museo de Ciencias Naturales, Universidad Nacional de San Juan, Argentina (IMCN-UNSJ 5010). Verified by G. Blanco. Previously known from Jujuy, Formosa, Chaco, Corrientes, Cordoba, Salta, Santiago del Estero, Santa Fe, La Rioja flats westward and San Luis provinces in Argentina (Cei 1980. Mon. II Mus. Reg. Sci. Nat. Torino, 609 pp.; Lavilla et al. 2000. Categorización de los Anfibios y Reptiles de la República Argentina. Asociación Herpetológica Argentina, 97 pp; Lavilla and Cei 2001. Mon. XXVIII Mus. Reg. Sci. Nat. Torino, 179 pp.). First province record, extends the known range ca. 150 km W of the nearest locality (Potrero de los Funes, San Luis Province) (Avila and Carrizo 2003. Acta Zool. Lilloana 47[1–2]:93–115; Lavilla and Cei 2001, *op. cit*.).

Submitted by **EDUARDO A. SANABRIA, LORENA B. QUIROGA,** and **JUAN C. ACOSTA,** Departamento de Biología e Instituto y Museo de Ciencias Naturales, F.C.E.F. y N., Universidad Nacional de San Juan, Avenida España 400 (N) C.P. 5400, San Juan, Argentina.

PLEURODEMA NEBULOSUM (Mendoza Four-eyed Frog). ARGENTINA: NEUQUÉN: Departamento Añelo (38°21'S, 68°47'W): Arroyo Ojos de Agua. 14 November 1976. O. de Ferrariis. Museo Argentino de Ciencias Naturales "Bernardino Rivadavia," Buenos Aires, Argentina (MACN 36078); Auca Mahuida (37°53'S, 68°31'W). April 1945. O. Adams (MACN 7980). Departamento Catan-Lil (39°33'S, 70°35'W): Charahuilla. 04 February 1973. O. de Ferrariis. Colección del Centro Nacional de Investigaciones Iológicas, housed at MACN (CENAI 7081). First province records, extends known distribution 275 km W from previous closest record (General Roca, La Pampa Province; Gallardo 1965. Rev. Mus. Arg. Cs. Nat. B. Rivadavia [Zool.], 1 [2]:57–77). SALTA: Departamento Cafayate (26°06'S, 65°57'W): Cafayate. 11 January 1991. J. McGuire. Fundación Miguel Lillo, Tucumán, Argentina (FML 5245); Cafayate, on Ruta Nacional Nº 68, between 8 and 12 km N of its intersection with Ruta Provincial Nº 40. 11 January 1991. R. Etheridge (FML 5246, three specimens); Cayafate, Los Médanos. 02 January 1993. N. Abdala (FML 5232, three specimens). Departamento San Carlos (25°53'S, 65°56'W): San Carlos, ca. 10 km E from Animaná. 04 January 1993. E. O. Lavilla (FML 5234, two specimens). First vouchered specimens reported, attributed to Salta Province by Lavilla (1999. Anfibios. *In* E. O. Lavilla and J. A. González [eds.], Biodiversity of Agua Rica, Catamarca, Argentina. Fund. M. Lillo - BHP Copper). Departamento Anta (24°55'S, 64°28'W): Finca Los Colorados. 13 January 2000. E. O. Lavilla and R. Heyer (FML 9094–96). First department record. Salta Province reports extends known distribution 350 km NE from previous closest record (Andalgalá, Catamarca Province; Lavilla 1999, *op. cit.*). TUCUMÁN: Departamento Tafí del Valle: Quilmes (26º30'S, 66º00'W). 18 January 1975. R. Laurent and C. Halloy (FML 2427, 43 specimens). New province record, referred to by Laurent as Tucumán Province (1969. Acta Zool. Lilloana 25[7]:81–96). This report extends known distribution 102 km NE from previous closest record (Andalgalá, Catamarca Province; Lavilla 1999, *op. cit.*). Boundary between CATAMARCA and TUCUMÁN Provinces: Arroyo los Médanos, between Santa María and Amaicha del Valle. 20 January 1975. R. Laurent and C. Halloy (FML 2425, 3 specimens); ca. 10 km from bridge of Santa María River. 25 January 1975. R. Laurent and C. Halloy (FML 2429, 2 specimens). New record for this area, extends known distribution ca. 111 km N from previous closest record (Andalgalá, Catamarca Province; Lavilla 1999, *op. cit.*). All specimens verified by Esteban O. Lavilla. The previous geographical range of this species includes the western Argentine provinces from Catamarca to Río Negro (Aun and Martori 1999. Herpetol. Rev. 30[4]:231; Cei 1980. Amphibians of Argentina. Monit. Zool. Ital. [N.S.] Monogr. 2: [i-xii] + 1–609) and Tucumán Province (Laurent 1969, *op. cit.*).

Submitted by **DAIANA PAOLA FERRARO**, Sección Herpetología, División Zoología Vertebrados, Museo de La Plata, Paseo del Bosque S/N° (1900) La Plata, Buenos Aires, Argentina; e-mail: dferraro@fcnym.unlp.edu.ar.

PSEUDACRIS FERIARUM FERIARUM (Upland Chorus Frog). USA: TEXAS: LA SALLE CO.: Approximately 12 km E of Cotulla on Hwy 97, ca. 30 m S of the highway. 13 March 2004. Joshua R. Engelbert and Robert C. Jadin. Verified by Jonathan A. Campbell. UTA – Collection of Vertebrates (UTA Slide No. 31331–32). Caught in small flooded area about an hour before sunset, during intermittent rain. Photographed and released. New county record (Dixon 2000. Amphibians and Reptiles of Texas. 2nd Ed. Univ. of Texas A&M Press, viii + 421 pp.).

Submitted by **ROBERT C. JADIN** (e-mail snakeman1982@hotmail.com) and **JOSHUA R. ENGELBERT**, Northeastern State University, Tahlequah, Oklahoma 74464, USA (e-mail: okieherper@yahoo.com).

PSEUDIS PARADOXA (NCN). VENEZUELA: FALCÓN: MUNICIPIO MAUROA: embalse de Matícora (10°40'N, 70°55'W). 28 January 2000. T. Barros. Museo de Biología de La Universidad del Zulia, Maracaibo (MBLUZ-A-0102). Verified by G. Rivas Fuenmayor. The species occurs east of the Andes from Colombia, Venezuela and the Guianas to northern Argentina. (La Marca 1992, Catálogo Taxonómico, Biogeográfico y Bibliográfico de las Ranas de Venezuela, Cuadernos Geográficos, No. 9, Universidad de Los Andes, Mérida, 197 pp.). In Venezuela it has a wide distribution in the lowland savannas below 300 m (Barrio 1998. Acta. Biol. Venez. 18[2]:1–93; Gorzula and Señaris 1998. Contribution to the Herpetofauna of the Venezuelan Guayana I. A Data Base, Scientia Guaianae, No. 8, Caracas, 269 pp.; Pefaur and Rivero 2000. Amph. Rept. Cons. 2[2]:42–70; Rivero 1964. Carib. J. Sci. 4[1]:307–319). First state record and northernmost locality for the country, extends known range ca. 130 km N from La Ceiba in Trujillo state (Barrio, *op. cit.*).

Submitted by **FERNANDO ROJAS RUNJAIC** (e-mail: rojas_fernando@hotmail.com), **TITO BARROS BLANCO** (e-mail: trbarros@cantv.net), and **EDWIN INFANTE RIVERO (**e-mail: edwinfantembluz@hotmail.com), La Universidad del Zulia, Facultad Experimental de Ciencias, Museo de Biología de La Universidad del Zulia, Sección de Herpetología, Apartado Postal 526, Maracaibo 4011, Venezuela.

PSEUDIS TOCANTINS (NCN). BRAZIL: MARANHÃO: MUNICIPALITY OF PORTO FRANCO: 'Fazenda Maravilha' (06º00'38.2"S, 47º25'43.9"W), 162 m elev. 07 January 2005. E. M. Lucas. Célio F. B. Haddad collection, Departamento de Zoologia, Universidade Estadual Paulista, Rio Claro, São Paulo (CFBH 8132). Verified by C. F. B. Haddad. Species previously known from type locality, Municipality Porto Nacional, state of Tocantins, Brazil (10º42'S, 48º25'W, 212 m elev., Caramaschi and Cruz 1998. Rvta. Brasil. Zool. 15:929–944); Bananal Island National Park region (10º28'12"S, 50º28'48"W), Municipality of Santa Terezinha, State of Mato Grosso, and Municipality of Britania (15º14'34"S; 51º 10'44"W), state of Goias, Brazil (Brandão et al. 2003. Phyllomedusa 2:69–70). First state record, extends the distribution ca. 595 km N from type locality in Tocantins State.

Submitted by **ELAINE M. LUCAS**, Departamento de Ecologia, Universidade de São Paulo, CP 11461,CEP 05508-900, São Paulo, Brazil; and **CINTHIA A. BRASILEIRO**, Museu de História Natural, Instituto de Biologia, Universidade Estadual de Campinas, CP 6109, 13083-970 Campinas SP, Brazil (e-mail: elainelg@ib.usp.br).

RANA PALMIPES (Amazon River Frog). BRAZIL: ALAGOAS: Passo de Camarajibe (09°15'S, 35°26'W). 13–17 January 1988. H. R. Silva, L. C. Carcerelli, C. C. Geovannini, and D. Teixeira. Museu Nacional - Universidade Federal do Rio de Janeiro. Rio de Janeiro, Brazil (MNRJ 9903). 26–30 June 1988. D. Teixeira. (MNRJ 9797). Murici (09°19'S, 35°56'W). 8 January 1988. D. Teixeira, H. R. Silva, L. C. Carcerelli, C. A. Caetano, L. Geovannini, and L. A. Caetano. (MNRJ 9725). BAHIA: Caravelas (17°45'S. 39°15'W). 1876. Rathbun (Comm. Geol. do Brasil). (MNRJ 494). MATO GROSSO: Matupá (10º03'S, 54º58'W). 6 March 1990. C. Yamashita. (MNRJ 35796–97). PARÁ: Cachimbo (08°57'S, 54°54'W). 25 September – 9 October 1956. L. Travassos, Oliveira, and Adão col. (MNRJ 3319, 13764–71). Jacareacanga (06°16'S, 57°39'W). July 1951. H. Sick. (MNRJ 35795). All verified by José P. Pombal, Jr. The species has a broad distribution in northern South America (Miranda-Ribeiro 1923. Rev. Mus. Paulista 13:801–809), but published data are lacking for most of Brazilian Amazon according to Bernardi et al. 1999. Herpetol. Rev. 30:176–177. The species occurs in Bolivia, Brazil, Colombia, Ecuador, Guyana, French Guyana, Peru, Trinidad, and Venezuela. In Brazil, the published distribution is limited to states of Amazonas, Mato Grosso, Pará, Paraíba, Pernambuco, and Rio Grande do Norte (Bernardi et al. 1999, *op.cit*; Hillis and de Sá 1988. Herpetol. Monogr. 2:1–26; Strussmann and Carvalho 1998. Herpetol. Rev. 29:183–185). Herein, we present the first state records for Alagoas and Bahia, northeastern Brazil. These new records extend by ca. 1170 km the southern range limits for this species in northeastern Brazil. The other records corroborate occurrence of the species in the Brazilian Amazon.

Submitted by **CLARISSA CANEDO** and **MARCOS BILATE**, Departamento de Vertebrados, Museu Nacional/UFRJ, Quinta da Boa Vista s/n, São Cristovão, Rio de Janeiro, RJ, Brazil, 20940–040; e-mail: canedo@mn.ufrj.br.

RANA SPHENOCEPHALA (Southern Leopard Frog). USA: ARKANSAS: CLEVELAND CO: Roadside ditch 5.1 km SW of Rison, AR (Sec. 27, T9S, R11W). 20 May 2005. H. W. Robison. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 29327). Verified by Stanley E.Trauth. New county record in southern Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville).

Submitted by **HENRY W. ROBISON** and **JANET RADER**, Department of Biological Sciences, Southern Arkansas University, Magnolia, Arkansas 71754-9354, USA; e-mail: hwrobison@saumag.edu.

RHACOPHORUS ORLOVI (Orlov's Tree Frog). VIETNAM: GIA LAI PROVINCE: AN KHE DISTRICT: Buon Luoi Village, 20 km NW of Kannack Town (14°20'N, 108°36'E), on leaf of an Araceae plant near a stream, 700–750 m elev., 1700–1900 h, 06 April 1995. Nikolai L. Orlov and Ilya Darevsky. FMNH 253156. Verified by Robert F. Inger. First record for southern Vietnam. Known previously from Ninh Binh, Nghe An, Ha Tinh (type locality), and Quang Binh Provinces in northern and central Vietnam (Ziegler and Köhler 2001. Sauria 23:37–46; Orlov et al. 2002. Russ. J. Herpetol. 9:81–104; Ziegler et al. 2002. Herpetol. Rev. 33:146). This record extends the known range of the species at least 350 km southward. This specimen was reported as

Rhacophorus bimaculatus (type locality Mindanao, Philippines) by Inger et al. 1999 (Fieldiana, Zool., N.S. 92:1–46) and Orlow and Ho (2000. Herpetofauna 22:5–15), and is illustrated in life in the latter reference. Ziegler and Köhler (2001. Sauria 23:37–46) did not examine this specimen, but suggested that it might be referable to *R. cyanopunctatus* (type locality Surat Thani Province, southern Thailand) based on its locality. Other records of *R. bimaculatus* from Vietnam (Gia Lai and Kon Tum Provinces in Orlov et al. 2002. Russ. J. Herpetol. 9:81–104) might also refer to *R. orlovi*. Orlov et al. 2002 (Russ. J. Herpetol. 9:81–104) remarked that *R. bimaculatus*, *R. cyanopunctatus*, *R. hoanglienensis* (type locality Lao Cai Province, northern Vietnam), and *R. orlovi* form a complex of closely-related species, and this might account for misidentifications.

Submitted by **BRYAN L. STUART**, The Field Museum, Department of Zoology, 1400 S. Lake Shore Drive, Chicago, Illinois 60605-2497, USA; e-mail: bstuart@fieldmuseum.org.

SPEA INTERMONTANA (Great Basin Spadefoot) USA: OREGON: Union Co.: (45°15'885"N, 117°57'574"W, 845.5 m elev.). 13 May 2005. Laura A. Mahrt. Verified by Burr Betts. Eastern Oregon University Vertebrate Museum (A05-1). New county record (Leonard et al. 1993. Amphibians of Washington and Oregon, Seattle Audubon Society, Seattle.168 pp.).

Submitted by **LAURA A. MAHRT**, Science Office, One University Blvd., Eastern Oregon University, La Grande, Oregon 97850, USA (e-mail: lmahrt@eou.edu); and **M. CATHY NOWAK** Ladd Marsh Wildlife Area, 59116 Pierce Road, La Grande, Oregon 97850, USA (e-mail: mcnowak@eoni.com).

SCINAX FUSCOVARIUS (Snouted Treefrog). ARGENTINA: CATAMARCA: El Alto Departament: Rosario de Abajo (ca. 28º37'S, 65º25'W), 500–750 m elev. 5 February 2004. D. Baldo and S. D. Rosset. Verified by G. R. Carrizo. Herpetological collection Museo de La Plata, La Plata, Buenos Aires, Argentina (MLP-DB 2666–2667). Male and female in amplexus, found on the bank of a small stream in the Sierra de Ancasti. Species previously known from Corrientes, Chaco, Entre Ríos, Formosa, Jujuy, Misiones, Salta, Santiago del Estero, Santa Fe, and Tucumán (Lavilla et al. 2000. *In* Lavilla et al. [eds.], Categorización de los Anfibios y Reptiles de la República Argentina, pp. 11–34, Edición Especial Asociación Herpetológica Argentina, Tucumán, Argentina). First province record, extends the species range ca. 80 km S from Tucumán (Lavilla et al., *op. cit.*).

Submitted by **DIEGO BALDO**, Laboratorio de Genética Evolutiva y Molecular, Departamento de Genética, Facultad de Ciencias Exactas, Químicas y Naturales, Universidad Nacional de Misiones, Félix de Azara 1552, 3300 Posadas, Misiones, Argentina, and **SERGIO D. ROSSET**, Instituto de Limnología "Dr. Raúl A. Ringuelet" cc 712, 1900 La Plata, Buenos Aires, Argentina.

TESTUDINES

ACANTHOCHELYS MACROCEPHALA (Pantanal Swamp Turtle). BRAZIL: MATO GROSSO DO SUL: Corumbá (Nhumirim Farm: 18°57'S, 56°37'W) and Aquidauana (Rio Negro Farm: 19°34'S, 56°14'W). 1–15 October 2002. M. A. Kinas and F. L. Souza. Verified by A. S. Abe. Zoological Collection of Department Biology, Universidade Federal de Mato Grosso do Sul, Brasil (ZUFMS-CHEL: 0001–0007). Intact carapace, plastron and bones found around bays and salt lagoons. These are the first species records for Mato Grosso do Sul State, better defining the Paraguay River basin as the core geographical distribution area for this species. These records are ca. 260 km straightline south from Mato Grosso State and 290 km N of Puerto Casado, Paraguay, the closest locality records (Rhodin et al. 1984. Herpetologica 40:38–46).

Submitted by **MARCO AURÉLIO KINAS**, Universidade Federal de Mato Grosso do Sul, Centro de Ciências Biológicas e da Saúde, Departamento de Biologia, 79070-900, Campo Grande, Mato Grosso do Sul, Brazil; **RODINEY DE ARRUDA MAURO**, Empresa Brasileira de Pesquisa Agropecuária, Caixa Postal 154, 79002-970, Campo Grande, Mato Grosso do Sul, Brazil; and **FRANCO LEANDRO SOUZA**, Universidade Federal de Mato Grosso do Sul, Centro de Ciências Biológicas e da Saúde, Departamento de Biologia, 79070-900, Campo Grande, Mato Grosso do Sul, Brazil (e-mail: flsouza@nin.ufms.br).

CUORA GALBINIFRONS (Indochinese Box Turtle). VIETNAM: LAO CAI PROVINCE: Van Ban District: Hoang Lien Mountain Range: Nam Tha forest, 21°55'23"N, 104°22'43"E, ca. 640 m elev. 01 September 2004. Raoul H. Bain, Nguyen Quang Truong, and Doan Van Kien. Institute of Ecology and Biological Resources (IEBR 1497, with field tag AMNH FS-16418). Verified by Bryan L. Stuart. In Vietnam, this species has been reported only from some central and northeastern provinces. This is the first record for northwestern Vietnam including Lao Cai Province (Nguyen et al. 1996. A Checklist of Amphibians and Reptiles of Vietnam. Agricultural Publishing House of Vietnam, Hanoi, pp. 115–116).

Submitted by **NGUYEN QUANG TRUONG** and **DOAN VAN KIEN**, Department of Vertebrate Zoology, Institute of Ecology and Biological Resources, 18 Hoang Quoc Viet, Hanoi, Vietnam; and **RAOUL BAIN**, Center for Biodiversity and Conservation, American Museum of Natural History, Central Park West at 79th Street, New York, New York 10024, USA.

AMPHISBAENIA

AMPHISBAENA DUBIA (Uncertain Worm Lizard): BRAZIL: MINAS GERAIS: Ritápolis (20°59'47"S, 44°16'20.5"W). 07 December 2002, collector unknown. Coleção Herpetológica, Universidade Federal de Juiz de Fora, Juiz de Fora, Minas Gerais (CH-UFJF 209). Verified by S. Potsch de Carvalho e Silva. Previously known from Santa Catarina, Paraná, and São Paulo States, Brazil, and Formosa, Argentina (Gans 1964. Breviora 205:1–11; Montero 1996. Cuad. Herpetol. 10[1–2]:25–45; Vanzolini 2002. Papéis Avulsos Zool. S. Paulo 42[15]:351–362). First state record, extends known distribution ca. 230 km NE from Campos do Jordão, São Paulo State, the nearest previously known locality (Gans 1964, *op. cit.*)

Submitted by **JOSÉ DUARTE DE BARROS FILHO**, Laboratório de Anfíbios e Répteis, Universidade Federal do Rio de Janeiro, Rio de Janeiro-RJ, Cx.P. 68044, CEP 21944-970, Brazil (e-mail: jduartef@biologia.ufrj.br); **BERNADETE MARIA DE SOUSA** (e-mail: bernadete.sousa@ufjf.edu.br) and **ROSE MARIE HOFFMANN DE CARVALHO** (e-mail: rosemarie@acessa.com), Laboratório de Herpetologia, Universidade Federal de Juiz de Fora, Minas Gerais, Brazil.

LACERTILIA

ANOLIS CAROLINENSIS CAROLINENSIS (Northern Green Anole). USA: ARKANSAS: CHICOT CO.: Lake Village city limits (Sec. 3, T16N, R2W). 30 May 2005. H. W. Robison. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 29328). Verified by Stanley E.Trauth. New county record in extreme southeastern Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville).

Submitted by **HENRY W. ROBISON** and **JANET RADER**, Department of Biological Sciences, Southern Arkansas University, Magnolia, Arkansas 71754-9354, USA; e-mail: hwrobison@saumag.edu.

ANOLIS PENTAPRION (Lichen Anole). MÉXICO: VERACRUZ: MUNICIPALITY OF LAS CHOAPAS: Batería Los Soldados (17°57'49.4"N; 94°06'52.2"W), 7 m elev. 5 July 2003. José Luis Aguilar López. Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México (MZFC 16574). Verified by Edmundo Pérez Ramos. Second record for Veracruz and bridges the distributional gap between recorded localities in the Los Tuxtlas region, ca. 132 km to the NE, and records ca. 225 km ESE from near Palenque, Chiapas (Lieb 2001. *In* Johnson et al. [eds.], Mesoamerican Herpetology: Systematics, Zoogeography, and Conservation, pp. 53–64. Centennial Mus. Spec. Publ. No. 1, University of Texas at El Paso). The specimen was found on a tree branch in a tropical semideciduous forest.

Submitted by **JOSE LUIS AGUILAR LÓPEZ**, Laboratorio de Herpetología, Escuela de Biología, Benemérita Universidad Autónoma de Puebla, C.P. 72570, Puebla, México (e-mail: bothrops_asper@hotmail.com); **LUIS CANSECO MÁRQUEZ** (e-mail: lcm@correo.unam.mx) and **URI OMAR GARCÍA VÁZQUEZ**, Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México, A.P. 70-399, México, D.F. 04510, México.

ANOLIS SAGREI (Brown Anole). USA: FLORIDA: OKALOOSA CO: Fort Walton Beach, Uptown Station shopping center, 99 Eglin Parkway (FL Hwy 85), 30°25'9"N, 86°36'22"W. 16 July 2002. David C. Bishop. Verified by Kenneth Krysko. University of Florida (UF 133632, 133633). New county record (Campbell 1996. Herpetol. Rev. 27:155–157). Male and female captured in copulation. Another female and four juveniles observed.

Submitted by **DAVID C. BISHOP**, Department of Fisheries and Wildlife Sciences, Virginia Tech University, Blacksburg, Virginia 24061-0321, USA; e-mail: dabishop@vt.edu.

BACHIA HETEROPA LINEATA (NCN). VENEZUELA: TRUJILLO: MUNICIPIO PAMPANITO: Urbanización "El Prado" (9°25'N, 70°27'W), 480 m. 20 November 2002. C. Cuevas. Museo de Biología de La Universidad del Zulia, Maracaibo (MBLUZ-R-0763). Specimen found on sandy ground in residential garden. ZULIA: MUNICIPIO JESÚS MARÍA SEMPRÚN: Casigua-El Cubo (8°45'N, 72°30'W). 12 August 1965. R. Hernández. Museo de Historia Natural La Salle, Caracas (MHNS 2497). Both verified by G. Rivas. The distribution of this subspecies is restricted to Venezuela (Dixon 1973. Univ. Kansas, Mus. Nat. Hist., Misc. Publ. [57]:47 pp.). The previously known range included the Capital District and Falcón, Yaracuy, and Portuguesa states (Dixon, *op. cit*.; Donoso-Barros 1968. Carib. J. Sci. 8[3–4]:105–122; Esqueda et al. 2001. Herpetol. Rev. 32[3]:198–200; Markezich 2002. Herpetol. Rev. 33[1]:69–74; Mijares and Arends 1999. Herpetol. Rev. 30[2]:115). First records for these two states of the Maracaibo Lake Basin, and the westernmost localities for the subspecies. MHNS 2497 extends the distribution ca. 210 km W (airline) from the nearest known locality (Markezich, *op. cit*.).

Submitted by **FERNANDO ROJAS** (e-mail: rojas_fernando@hotmail.com) and **EDWIN INFANTE (**e-mail: edwinfantembluz@hotmail.com), La Universidad del Zulia, Facultad Experimental de Ciencias, Museo de Biología de La Universidad del Zulia, Sección de Herpetología, Apartado Postal 526, Maracaibo 4011, Venezuela.

CHALCIDES OCELLATUS OCELLATUS (Ocellated Skink). LIBYA: NAULT PROVINCE (Sha'abeyyat Nalut): Ain Al-Khenjari (31°59'33"N, 11°36'12"E). Collected from an oasis ca. 190 km SW of Tripoli. 21 March 2004. Asmaa Mohammad Ali. Muséum National d'Histoire Naturelle, Paris (MNHN 2004.0084). SVL = 97 mm. Verified by Ivan Ineich. Several other individuals were also collected from the same locality during spring and summer. First provincial record (Schleich et al. 1996. Amphibians and Reptiles of North Africa. Koeltz Scientific Publishers, Koeningstein; Frynta et al. 2000. Acta. Soc. Zool. Bohem. 64:17–26).

Submitted by **ADEL A. IBRAHIM,** Faculty of Education at Al-Arish, Suez Canal University, North Sinai, Egypt; e-mail: Laudakia@hotmail.com.

CNEMIDOPHORUS LONGICAUDA (Long-tailed Whiptail). ARGENTINA: CHUBUT: TELSEN: Sand flats along Telsen stream, on the edges of Ruta Provincial 61, 40.3 km S junction Ruta Provincial 1 (42°44'48.8"S, 66°59'54.8"W, 117 m elev.). 02 February 2005. N. Frutos and L. Camporro. Herpetological Collection Museo de La Plata, La Plata, Buenos Aires (MLP.S 2584). Verified by N. Basso. First province record (Cei 1986. Mon. IV. Mus. Reg. Sc. Nat. Torino: 1–427), and southernmost record for the species, extending known range 238 km S (airline) from Valcheta, Rio Negro province (Cabrera 2004. Amphibia-Reptilia 25:265–275).

Submitted by **NICOLAS FRUTOS** (e-mail: frutos@cenpat.edu.ar), **LEONARDO CAMPORRO** (e-mail: leocamporro@hotmail.com), and **LUCIANO JAVIER AVILA (**e-mail: avila@cenpat.edu.ar), CENPAT-CONICET, Boulevard Almirante Brown s/n, U9120ACV, Puerto Madryn, Chubut, Argentina.

EUTROPIS LONGICAUDATA (Long-tailed Sun Skink). MYANMAR: MANDALAY DIVISION: PYIN-OO-LWIN DISTRICT: Tha Baik Kyin Town, Shwe-U-Daung Wildlife Sanctuary (headquarters) (22°53'29.3"N, 95°59'27.7"E, WGS84). 28 September 2000. Htun Win and San Lwin Oo. California Academy of Sciences (CAS) 216129. SHAN STATE: YWANGAN TOWNSHIP: Panlaung-Pyadalin Cave Wildlife Sanctuary, entrance to Pyadalin Cave (21°07'58.4"N, 96°20'25.0"E, WGS84). 14 July 2002. Rhonda S. Lucas, Guin O.U. Wogan, Jens V. Vindum, Htun Win, Thin Thin, Kye Soe Lwin, Awan Khwi Shein, and Hla Tun. CAS 230469. SHAN STATE: YWANGAN TOWNSHIP: Panlaung-Pyadalin Cave Wildlife Sanctuary (21°07'17.3"N, 96°21'19.1"E, WGS84).

Rhonda S. Lucas, Guin O.U. Wogan, Jens V. Vindum, Htun Win, Thin Thin, Awan Khwi Shein, and Hla Tun. CAS 230538. All identifications verified by George R. Zug. New country record. Given that *E. longicaudata* (formerly known as *Mabuya longicaudata*: see Mausfeld et al. 2002. Zool. Anz. 241:281–293) occurs in a broad area of southeastern Eurasia and adjacent islands, including Taiwan, Hong Kong, Hainan, southern continental China, and parts of Southeast Asia (Manthey and Grossmann 1997. Amphibien und Reptilien Südostasiens. Natur und Tier–Verlag, Münster, 512 pp.; Taylor 1963. Univ. Kansas Sci. Bull. 44:687–1077), the species might actually represent a complex of more than one morphologically similar species. Further detailed studies examining both morphological and genetic variation among samples from throughout the entire range of *E. longicaudata* are needed.

Submitted by **MARLENE GONZALEZ**, University of San Francisco, College of Arts and Sciences, 2130 Fulton Street, San Francisco, California 94117, USA; and **JENS V. VINDUM**, Department of Herpetology, California Academy of Sciences, 875 Howard Street, San Francisco, California 94103, USA.

LIOLAEMUS OLONGASTA (NCN). ARGENTINA: MENDOZA: Departamento Las Heras: 60 km Mendoza city on Puesto Sta. Clara de Abajo, Ruta Provincial N° 319 (32º40'S, 69º10'W), January 2004. L. Quiroga and E. Sanabria, Herpetological Collection, Instituto y Museo de Ciencias Naturales, Universidad Nacional de San Juan, Argentina (IMCN-UNSJ 5009). Verified by G. Blanco. This species is distributed in two localities in extreme western La Rioja Province at elevations between 900 and 1600 m and west of San Juan Province to the Cerrillo Barboza (Etheridge 1993. Boll. Mus. Reg. Sci. Nat. Torino 11[1]:137–199; Avila et al. 1998. Cuad. Herpetol. 12[1]:11–29). First province record. Extends known range (Avila et al. 1998, *op cit.)* ca. 75 km SW of the nearest locality (Cerrillo Barboza, Departmento Rawson, San Juan Province).

Submitted by **EDUARDO A. SANABRIA, LORENA B. QUIROGA,** and **JUAN C. ACOSTA,** Departamento de Biología e Instituto y Museo de Ciencias Naturales, F.C.E.F. y N., Universidad Nacional de San Juan, Avenida España 400 (N) C.P. 5400, San Juan, Argentina.

MESOSCINCUS ALTAMIRANI (Tepalcatepec Skink). MÉXICO: MICHOACÁN: Municipality of Huetamo: Rancho El Zipiate, 8 km from the west bank of the Río Balsas (18°37'03"N, 100°54'54"W), 330 m elev. 04 November 2003. D. Suazo and J. Alvarado. Colección Herpetologica, Instituto de Investigaciones sobre los Recursos Naturales, Universidad Michoacana (HINIRENA 452). GUERRERO: Municipality of Zirandaro: Rancho El Tecolote, 500 m from the east bank of the Río Balsas (18°30'48"N, 101°00'37"W), 215 m elev. 27 March 2004. D. Suazo and I. Suazo. HINIRENA 481 . Both specimens verified by Alfredo Estrada-Virgen.

Each specimen was found in the southern part of the Río Balsas Basin and both represent substantial range extensions for the species. HINIRENA 481 is the first record from Guerrero and is a ca.180 km range extension NW from nearest known record at the type locality, Apatzingán, Michoacán. The location of HINIRENA 452 is ca.155 km SE of the type locality. Both skinks were located in areas containing tropical dry forest.

SCINCOPUS FASCIATUS FASCIATUS (Banded Skink). LIBYA: NAULT PROVINCE (Sha'abeyyat Nalut): Badr Village (32º02'27"N, 11º32'38"E). Collected from a farm ca. 200 km SW of Tripoli. 2 March 2004. Amna Al-Bahi. Muséum National d'Histoire Naturelle, Paris (MNHN 2004.0081). SVL = 149 mm. Verified by Ivan Ineich. First provincial record (Frynta et al. 2000. Acta. Soc. Zool. Bohem. 64:17–26) and second country record (Sindaco 1995. Bull. Mus. Reg. Sci. nat. Torino, pp. 117–122; Schleich et al. 1996. Amphibians and Reptiles of North Africa. Koeltz Scientific Publishers, Koeningstein). The known range of this species extends from south Mauritania to Sudan (Schleich et al. 1996, *op. cit.*). This is the only specimen of the species collected during a survey from November 2003 to July 2004.

Submitted by **ADEL A. IBRAHIM** Faculty of Education at Al-Arish, Suez Canal University, North Sinai, Egypt; e-mail: Laudakia@hotmail.com.

SPHENOMORPHUS INCERTUS (Stuart's Forest Skink). HONDURAS: CORTÉS: Sierra de Omoa, Parque Nacional El Cusuco, near Centro de Visitantes (15º30'N, 88º13'W), 1570 m elev. 2 March 2005. Josiah H. Townsend. Florida Museum of Natural History (UF 144061). Verified by Kenneth L. Krysko. First record for Cortés, Parque Nacional El Cusuco, and the Cordillera de Merendón (Wilson and McCranie 2004. Herpetol. Bull. 87:13–24), and bridges a distributional gap between localities located 100 km E in Refugio de Vida Silvestre Cerro Texíguat, Yoro, Honduras (Wilson and McCranie 1994. Amphibia-Reptilia 15:416–421) and 185 km W near Purulha, Baja Verapaz, Guatemala (KU 187230–32). The skink was found on a trail going through mixed pine-broadleaf forest.

BOTHROPS PUNCTATUS (Chocoan Forest Pitviper). COLOMBIA: DEPARTAMENTO DE ANTIOQUIA: Municipality of Yolombó: Quebrada La Cancana (6°48'N, 75°06'W) ca. 1000 m. elev. 09 May 1997. J. Aubad. Museo de Herpetología Universidad de Antioquia, Medellín, Colombia (MHUA 10041, adult male). Municipality of Amalfi: 6°53'N, 75°09'W. 04 Oct 1990. J. Asprilla. Serpentario Universidad de Antioquia, Medellín, Colombia (SUA 552). Municipality of San Luis (6°02'N, 74°59'W). 13 Jul 1990. (SUA 483). 22 Apr 1997. J. Asprilla (SUA 2220). Verified by W. W. Lamar. This species has been considered endemic from Chocoan lowland rainforest from eastern Panama to northwestern Ecuador (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell University Press). The easternmost record in Colombia is Municipality of Urrao (Antioquia) on the Cordillera Occidental. First record for Cordillera Central, it documents the occurrence of the species in the Río Cauca and Río Magdalena Basins to eastern Chocó, and extends the distribution almost 125 km northeast and 130 km east from Urrao, a previously known locality in Antioquia (Campell and Lamar, *op. cit.*).

Submitted by **JUAN MANUEL DAZA-R.**, Grupo Herpetológico de Antioquia, Instituto de Biología, Universidad de Antioquia, oficina 7-121. CLELIA HUSSAMI (Mussurana). BRAZIL: RIO GRANDE DO SUL: São Francisco de Paula (29°02'S, 50°23'W), Floresta Nacional de São Francisco de Paula. 18 January 2004. R. Fleck. Coleção de Répteis, Museu de Ciências Naturais da Fundação Zoobotânica do Rio Grande do Sul (MCN.15175, female, 606 mm SVL + 80 mm tail). Verified by F. L. Franco. Previously reported only from Santa Catarina and Paraná states (Morato et al. 2003. Phyllomedusa 2:93–100). This record corroborates the suggested association of *C. hussami* to the Araucaria forest biome (Morato et al., *op. cit*.). First state record and southernmost record for the species, extends known distribution ca. 230 km airline S from Fraiburgo, Santa Catarina (Morato et al., *op. cit*.).

Submitted by **MÁRCIO BORGES-MARTINS (**e-mail: marciobmartins@fzb.rs.gov.br), **JONATAS GONÇALVES ROSSETTI**, and **ANA CAROLINA ANÉS**, Núcleo Regional de Ofiologia de Porto Alegre, Museu de Ciências Naturais da Fundação Zoobotânica do Rio Grande do Sul, Rua Dr. Salvador França, 1427, CEP 90690-000, Porto Alegre, Rio Grande do Sul, Brazil.

CONIOPHANES MERIDANUS (Peninsular Stripeless Snake). MEXICO: Quintana Roo: Municipality of Othón P. Blanco: Chetumal (18°30'22"N, 88°17'05"W). 01 February 2005. Magdalena Hernández and Pierre Charruau. Herpetological Collection, Museum of Zoology, El Colegio de la Frontera Sur, Chetumal, Quintana Roo (ECO-CH-H 2716). Verified by Gunther Köhler. Southernmost record for the species on the Yucatán Peninsula, extending the range ca. 80 km SW of the closest known locality in central Quintana Roo on road to Noh Bec, 15.6 km N of jct. with Hwy. 307 (Lee 1996. The Amphibians and Reptiles of the Yucatán Peninsula. Cornell University Press, Ithaca, New York. 500 pp.).

Submitted by **PIERRE CHARRUAU** (e-mail: rcedev@ecosur-qroo.mx) and **J. ROGELIO CEDEÑO-VÁZQUEZ (**e-mail: rogeliocv@mexico.com), El Colegio de las Frontera Sur, Unidad Chetumal, Av. Centenario km 5.5, 77900 Chetumal, Quintana Roo, México.

CORALLUS CANINUS (Emerald Tree Boa). COLOMBIA: ANTIOQUIA: Municipio de Cáceres: 7°35'N, 75°20'W, 500 m elev. 21 March 1994. A. Ramírez. Verified by R. Powell. Museo de Ciencias Naturales Universidad de Antioquia, Medellín, Colombia (MUAREP 001). The species has a wide distribution in the Guianas and Amazonia, but records from north or west of the

Andes have, until recently, lacked voucher specimens. First record from Depto. Antioquia, and second verified record from north of the Colombian Cordillera Central and Cordillera Occidental. This record and that of Renjifo and Lundberg (1999. Anfibios y Reptiles de Urrá. Ed. Colina, Medellín, Colombia) from Depto. Cordoba are the only documented records for the species north of the Colombian Andes. Present record extends the known distribution ca. 110 km SW of the Depto. Cordoba locality, and ca. 240 km NW of Muzo (Depto. Boyacá) on the western slope of the Cordillera Oriental.

LEPTOTYPHLOPS SALGUEIROI (Espirito Santo Blindsnake). BRAZIL: RIO DE JANEIRO: Municipality of Niterói: Itaipú (22º58'S, 43º03'W). 29 May 2005. C. C. Ratto. Museu Nacional – Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil (MNRJ 13124, adult male 211mm TL). Verified by P. Passos. The species occurs in southeastern Atlantic Rain Forest, in southern Bahia, Espírito Santo, and eastern Minas Gerais, Brazil (Passos et al. 2005. Bol. Mus. Nac., N. S., Zool., Rio de Janeiro 520:1–10). First state record. Extends range ca. 170 km S from Minas Gerais, municipality of Recreio (Passos et al. 2005, *op. cit.),* formerly the southernmost locality.

Submitted by **MARCOS BILATE** (e-mail: marcosbilate@ig.com.br) and **ELIZA RIBEIRO COSTA**, Museu Nacional, Universidade Federal do Rio de Janeiro, Departamento de Vertebrados. Quinta da Boa Vista, São Cristóvão, Rio de Janeiro, RJ, 20940-040, Brazil.

OPHEODRYS AESTIVUS (Rough Greensnake). USA: ARKANSAS: Lonoke Co.: 1 km E Cabot, Hwy. 38 (T4N, R9W, S8). 22 May 2005. Nick Goodwin and Jeff Shaver. Verified by Stanley E. Trauth. Arkansas State University Museum of Zoology Herpetological Collection (ASUMZ 29317). New county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **MICHAEL V. PLUMMER**, Department of Biology, Box 12251, Harding University, Searcy, Arkansas 72149, USA (e-mail: plummer@harding.edu); and **JEFF SHAVER,** Cabot High School, 401 North Lincoln, Cabot, Arkansas 72023, USA (e-mail: Jeff.Shaver@cps.k12.ar.us).

OPHEODRYS VERNALIS (Smooth Greensnake). USA: IOWA: Woodbury Co.: Owego Wetland Complex (42°16'72.3"N, 96°9'26.8"W). 24 June 2003. Christian Cox, Matthew Morrill, Aubrey Heupel, and Eugenia Farrar. Verified by Fredric Janzen. Iowa State University Research Collection ISUA-E-200520. New county record (Christiansen and Bailey 1994. Snakes of Iowa. Iowa Department of Natural Resources. Nongame Tech. Ser. No. 1, 16 pp.).

Submitted by **CHRISTIAN L.COX** (e-mail: nazg@iastate.edu), **EUGENIA S. FARRAR** (e-mail: esf@iastate.edu), Department of Ecology, Evolution and Organismal Biology, Iowa State University, Ames, Iowa 50011-3223, USA; and **JANE D. HEY**, Department of Biology, Morningside College, Sioux City, Iowa 51106, USA (e-mail: hey@morningside.edu).

PAREAS MARGARITOPHORUS (White-spotted Slug Snake). SINGAPORE: Khatib Bongsu (01˚25.993'N, 103˚51.207'E, ca. 7 m elev.). 26 December 2004. Benjamin Lee and Puay Koon Koh. Verified by Kelvin K. P. Lim. Raffles Museum of Biodiversity Research Zoological Reference Collection, The National University of Singapore (ZRC.2.6115). Adult, 350 mm in total length. Found crushed, probably by a motor vehicle, in a rural coastal area of degraded secondary forest and back mangrove. First specimen-based record from Singapore, also representing the southernmost extent of the species' range. In 2003 an individual snake, most likely belonging to this species, was found along Mandai Road and photographed, but was not collected (K. K. P. Lim, pers. comm.). Another individual of this species was found dead at Sungei Buloh Wetland Reserve on 15 April 2005. This individual, though measured (300 mm in total length) and photographed, was not collected (James W. M. Gan and K. K. P. Lim, pers. comm.). *Pareas margaritophorus* is distributed over continental Southeast Asia from southern China to northern Peninsular Malaysia (Cox et al. 1998. A Photographic Guide to Snakes and other Reptiles of Peninsular Malaysia, Singapore and Thailand. Asia Books, Bangkok, 144 pp.) as far south as Kedah and Kelantan (based on material at the Raffles Museum of Biodiversity Research: K. K. P. Lim, pers. comm.). The present record is unusual because this species has yet to be reported from southern Peninsular Malaysia. However, artificial introduction of the present specimen or other recent specimens (see above) is unlikely, because this species is apparently not traded commercially.

Submitted by **BENJAMIN LEE,** Central Nature Reserve, Conservation Division, National Parks Board, 601 Island Club Road, Singapore 578775 (e-mail: canopyben@gmail.com); and **PUAY KOON KOH**, National Parks Board HQ, 1 Cluny Rd, Singapore 259569.

REGINA GRAHAMI (Graham's Crayfish Snake). USA: IOWA: WOODBURY CO.: Owego Wetland Complex (42˚16'74.6"N, 96˚8'10.2"W). 24 June 2003. Christian Cox, Aubrey Heupel, and Eugenia Farrar. Verified by Fredric Janzen. Iowa State University Research Collection ISUA-E-200521. New county record (Christiansen and Bailey 1994. Snakes of Iowa. Iowa Department of Natural Resources. Nongame Tech. Ser. No. 1, 16 pp.).

Submitted by **CHRISTIAN L. COX** (e-mail: nazg@iastate.edu), **EUGENIA S. FARRAR** (e-mail: esf@iastate.edu), Department of Ecology, Evolution and Organismal Biology, Iowa State University, Ames, Iowa 50011-3223, USA; and **JANE D. HEY** (Department of Biology, Morningside College, Sioux City, Iowa 51106, USA (e-mail:hey@morningside.edu).

SISTRURUS CATENATUS TERGEMINUS (Western Massasagua). USA: TEXAS. ERATH CO.: 19 May 2001 at 1240 h an adult female was found DOR on county road 149 ca. 5.6 miles N of Hwy 377. 32˚25.83'N and 98˚02.05'W, 1053 ft elev. First county record (Dixon 2000. Amphibians and Reptiles of Texas, A&M University Press. 421 pp.). Verified by Eric N. Smith. University of Texas at Arlington Collection of Vertebrates (UTACV R 52937).

Submitted by **CARL J. FRANKLIN**. Amphibian and Reptile Diversity Research Center, The University of Texas at Arlington Department of Biology. Arlington, Texas 76019, USA (e-mail: Franklin@uta.edu); and **MICHAEL SMITH**, Dallas Fort Worth Herpetological Society, 7111 Layla Road, Arlington, Texas 76016, USA (e-mail: Masmith51@yahoo.com).

SONORA SEMIANNULATA (Groundsnake). USA: ARKANSAS: MARION CO.: ca. 3.6 km S AR Hwy 202, off County Road 113 (T20N, R15W, S01, SE1/4, NE1/4); (NAD 27 Conus) N36.44178, W92.53421. 15 April 2005. Joseph R. Milanovich. Verified by Chris T. McAllister. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 29257). New county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, 421 pp.) and the first verified Arkansas specimen collected since 1958 (Dowling 1958. Southwest. Nat. 27:228–230). This represents ca. 170 km eastern range extension within Arkansas and extends the range southward from Missouri (Johnson 2000. The Amphibians and Reptiles of Missouri. Missouri Dept. Conserv., Jefferson City. 400 pp.).

Submitted by **JOSEPH R. MILANOVICH, JANE ANFINSON, TROY J. BADER, RICHARD J. BAXTER, STEVE C. BRANDEBURA, SARAH A. DEVINEY, WAYLON R. HILER, JILL LEARNED, MICKEY W. MATTHEWS, CHARLES R. MCDOWELL, ROBERT G. NEAL, NATHAN T. STEPHENS, JOHN P. STEWART, BENJAMIN A. WHEELER,** and **STANLEY E. TRAUTH,** Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467-0599, USA; e-mail: strauth@astate.edu.

TRETANORHINUS MOCQUARDI (Swamp Snake). ECUADOR: PROVINCE OF ESMERALDAS: Atacames (00º52'12"N, 79º50'32"W, 8 m elev.), 13 and 25 February 1990, V. Cevallos and E. Kramer. Universidad San Francisco de Quito & Fundación Herpetológica G. Orcés, Quito, Ecuador (FHGO-USFQ 121–5, 187; collected at night in water, at a shrimp pond near coastline). Verified by J.-M. Touzet. The species was known from Panama, with no records from Colombia (Dunn 1939. Copeia [4]:212–217; Peters and Orejas-Miranda 1970. USNM Bull. 297). Uetz (1995–2005. The EMBL Reptile Database. Online. EMBL Heidelberg. <http://www.reptile-database.org>) mentioned the species from Ecuador, citing Almendáriz (1992 [1991]) *In* Barriga et al. [eds.], Lista de Vertebrados de Ecuador. Revista Politécnica, Quito XVI [3]:89–162); however, the author does not mention the species in that paper, nor subsequent lists (Coloma et al. 2000–2004. Reptiles de Ecuador. Online. Museo de Zoología, PUCE Quito, Ecuador <http://www.puce.edu.ec/zoologia/>). First vouchered country record. Extends known distribution ca. 900 km S from nearest localities in Panama (Dunn, *op. cit.*).

Submitted by **DIEGO F. CISNEROS-HEREDIA**, Colegio de Ciencias Biológicas & Ambientales, Universidad San Francisco de Quito, Ave. Interoceánica y calle Diego de Robles, Campus Cumbayá, Edif. Maxwell. Casilla Postal 17-12-841, Quito, Ecuador; e-mail: diegofrancisco_cisneros@yahoo.com.

This new publication, co-authored by three experienced herpetologists from the Thai National Science Museum (Pathum Thani) is the first comprehensive list of Thai reptiles and amphibians giving details on their distribution within the country and aiming to list all provinces from which each taxon has been recorded so far. Before describing the contents of this new and welcome addition to the herpetological bibliography on Thailand, a remark should be made about its publication date. Although "September, 2000" is indicated in the book, it was actually not printed before 2004 (T. Chan-ard and Y. Chuaynkern, pers. comm.).

The practically-conceived, pocket-sized book includes a) an administrative map of Thailand (p. 3), with different colors grouping the provinces in five divisions, corresponding to north, west, center, east, southeast and south regions; b) a foreword by the Secretary General of the Thai Office of Environmental Policy and Planning (p. 4); c) a "compilers' note" (pp. 5–6); d) a table of contents, showing the orders and families of the taxa treated (pp. 7–8); e) two colour plates of amphibians (19 species) and four of reptiles (34 species), showing, among others, some rarely illustrated taxa like *Caluella guttulata* and *Glyphoglossus molossus* (Microhylidae), *Gehyra lacerata* (Gekkonidae) and *Tropidophorus microlepis* (Scincidae) (pp. 9–14), although with photographs of small size and average quality; f) a table of amphibian species (pp. 15–48); g) a table of reptile species (pp. 49–143); h) a short bibliography with 126 references (pp. 144–151). The tables are divided into four columns: 1) taxon/species; 2) common names (in English, and in Thai with transliteration into English); 3) "locality", giving the Thai regions and provinces of occurrence, often with indication of the district or locality – distribution outside Thailand is not given; 4) "reference", detailing the sources for the species records.

In the locality column, the provinces of occurrence are grouped in geographical areas: north, northeast, east, southeast, central, southwest, and south, i.e. more divisions than the six appearing on the map. Moreover, the grouping of provinces in the two tables does not correspond to that in the map (see for example the distribution of *Leptobrachium smithi* on pp. 16–17, where the provinces of Kanchanaburi, Phetchaburi, Prachuap Khiri Khan and Uthai Thani are referred to a "southwest" area). Another example, among many, is the placement of Hua Hin (Prachuap Khiri Khan Province) in southwestern Thailand on p. 104 and in southern Thailand on p. 105.

The amphibian table lists 132 species, which is lower than the number of species actually recorded in 2004. Chan-ard (2003), in his excellent photographic field guide on Thai amphibians, indeed included 141 species. Although the compilers' note indicates a total of 325 reptile species, the table actually includes 326. The most recent herpetological works included in the bibliography date back from 2001, so all recent major works and additions to the amphibian and reptile faunas were not included. Since 2000, many gecko species have been added to the fauna of Thailand: *Cnemaspis phuketensis* Das & Leong, 2004, *Cyrtodactylus chanhomeae* Bauer, Sumontha & Pauwels, 2003, *C. sumonthai* Bauer, Pauwels & Chanhome, 2002, *C. thirakhupti* Pauwels, Bauer, Sumontha & Chanhome, 2004 and *C. tigroides* Bauer, Sumontha & Pauwels, 2003, and *Dixonius hangseesom* Bauer, Sumontha, Grossmann, Pauwels & Vogel, 2004, as well as two skinks, *Tropidophorus latiscutatus* Hikida, Orlov, Nabhitabhata & Ota, 2002 and *T. matsuii* Hikida, Orlov, Nabhitabhata & Ota, 2002. Asian skinks long placed in the genus *Mabuya* are now refered to the genus *Eutropis* Fitzinger, 1843 following Mausfeld et al. (2002) and Mausfeld and Schmitz (2003). The snake list includes 177 species, while 181 species (and in total 185 species and subspecies) were listed by David et al. (2004). Three additional species and one genus have been added since: *Lycodon cardamomensis* (Pauwels et al. 2005), *Macrocalamus lateralis* (Chan-ard et al. 2002; David and Pauwels 2004) (Colubridae) and *Trimeresurus fucatus* (Vogel et al. 2004; all peninsular localities of *T. popeiorum* seem in fact referrable to *T. fucatus*) (Crotalidae). It should also be noted that the binomen *Boiga ocellata* Kroon, 1973 is a junior subjective synonym of *Boiga siamensis* Nootpand, 1971 (Pauwels et al. 2005), that Thai *Trimeresurus* "*stejnegeri*" were shown to be in fact *T. gumprechti* and *T. vogeli* (David et al. 2001, 2002), and that *Trimeresurus venustus* was clearly shown to be specifically distinct from *T. kanburiensis* (David et al. 2004). Thai populations of *Psammophis condenarus* (sic) (Merrem, 1820) should be better regarded as *Psammophis indochinensis* Smith, 1943 (Pauwels et al. 2003).

The subspecific level is not considered in the tables. However, it would have stressed the existence of some endemic subspecies (endemic species are marked with an asterisk and, according to the foreword, this list is aimed to contribute to biodiversity conservation), notably *Draco maculatus divergens* Taylor, 1934 (known only from Chiang Mai Province), *Eutropis macularia malcolmi* (Taylor & Elbel, 1958), *E. m. postnasalis* (Taylor & Elbel, 1958) and *E. m. quadrifasciata* (Taylor & Elbel, 1958) (all three of doubtful but unresolved taxonomic status; still to be conservatively considered endemic to Loei Province), *Elaphe porphyracea*

coxi Schulz & Helfenberger, 1998 (Chaiyaphum and Loei provinces), and *Gongylosoma baliodeirum cochranae* (Taylor, 1962) (Chanthaburi Province).

The main weakness of this opus is the lack of documentation for the species records. For 75 of the 132 amphibian species, one finds "per. com." sources, by the three authors (!) and six other persons. The records of 28 amphibian species (21% of all 132 species) are even exclusively based on "personal communications", thus without any reference to a published work or museum collection material. In addition, the source for *Leptolalax gracilis* is a reference that is not listed in the bibliography. For some of these 28 species, Thai material was however published, and all 28 except *Rana andersonii* were treated and illustrated by Chan-ard (2003). The only source indicated for *Chaperina fusca* is "Taksintham (per. com.)"; the species was mentioned as *Chaperina* cf. *fusca* by Chan-ard (2003), thus expressing some doubt as to its identity. The source for *Kaloula baleata* is indicated as "Chan-ard (per. com.); Nabhitabhata (per. com.)" and the species is said to occur in the provinces of Krabi, Phuket, Ratchaburi, Surat Thani, Trang and Yala. One of the authors however co-authored a paper studying specimens from the provinces of Phang-Nga, Phuket and Trang (Pauwels et al. 1999). The records of *Rana milleti* from Chanthaburi, Chachoengsao, Nakhon Nayok and Nakhon Ratchasima provinces are indicated as originating from "per. com." by the three authors, without any other reference, but Chan-ard (2003) and Chuaynkern et al. (2004) reported specimens from the provinces of Chachoengsao, Nakhon Ratchasima and Ubon Ratchathani. What is called *Huia nasica* from Kanchanaburi Province was recently shown to be a distinct species, *Huia melasma* Stuart & Chan-ard, 2005. The problem of undocumented records is slightly less dramatic in reptile species. There are 271 species at least in part recorded on the basis of "per. com."; this is in fact the only source for 18 reptile species (by the authors or by a certain Damman), which represents 6 % of the total of 326 reptiles. Again, if literature had been better exploited, some published references could have been mentioned to justify many records. For instance, *Dogania subplana* is said to be based on a "per. com.", but among other references, Chan-ard et al. (1999) illustrated specimens from Surat Thani and Satun provinces. *Cyclemys tcheponensis*, listed on the basis of "Nabhitabhata (per. com.)", was however listed from Thailand, including Chiang Mai Province, on the basis of several specimens studied by Fritz and Ziegler (1999). The agamid *Pseudocalotes microlepis* is mentioned from three provinces, based on "per. com." but was already recorded from Thailand by Hallermann and Böhme (2000) (see also Pauwels et al. 2003). The record of *Fordonia leucobalia* is based only on "per. com.", but the species was already mentioned from Thailand by Frith and MacIver (1978). Idem for *Ahaetulla mycterizans*, listed, among others, by Chan-ard et al. (1999). The source for the record of *Lycodon butleri* is indicated as "Nabhitabhata (per. com.)"; however the species was mentioned twice by Cox (1991a-b), who indicated that the identification had been verified by J. Nabhitabhata. The record of *Ptyas fusca* is presented as known from "South (from animal dealer); Chan-ard (per. com.)", although the species was recorded from a precise locality by Pauwels et al. (2000). The records of the agamid *Bronchocela smaragdina*, the geckos *Cnemaspis flavolineata* and *Cyrtodactylus feae*, the skinks *Lipinia surda* and *Lygosoma corpulentum*, the colubrids *Oligodon catenatus* and *O. theobaldi*, *Stegonotus borneensis*, and of the sea snakes *Disteira nigrocinctus* and *D. obscurus*, and *Hydrophis inornatus*, based only on personal communications, definitely require confirmation through voucher material. *Hemidactylus b. brookii*, listed without any source from Thailand by Chan-ard et al. (1999) but confirmed from the country by Bauer et al. (2002), is not listed. Many of the records from Kaeng Krachan and Pala-U, in Phetchaburi and Prachuap Khiri Khan provinces, are based on material and observations gathered during field surveys in December 2002 and July 2004 and published by Pauwels and Chanard (2005).

Although we did not check each locality record, we noted some errors. *Cantoria violacea* is cited from Sai Yok, in Kanchanaburi, on the basis of "Gairder and Smith (1915)". These authors did not list *Cantoria violacea*, but *Simotes violaceus* Cantor, a synonym of *Oligodon cyclurus* Cantor, but long used for Thai and Indochinese populations in place of *Oligodon cinereus* (Günther, 1864) (see Smith 1943), which is the valid name for these populations. Many important distributional data on endangered species, such as *Chitra chitra* (Kitimasak and Thirakhupt 2002), *Pelochelys cantorii* (Pauwels et al. 2003), or *Crocodylus siamensis* (Platt et al. 2002), were published between 2000 and 2004.

Some references listed in the text are missing in the bibliography: Bohme (sic) (1982); Chuaynkern (2001) (pp. 45, 93); Cochran (1922) (p. 77); Colwell et al. (1977) (p. 105); Fritz and Bbst (sic) (1999) (p. 53); Grossmann (1992) (p. 235); Grossmann and Tillack (2001) (pp. 98, 111); Lauhajinda et al. (1999) (p. 17); Lauprasert and Thirakhupt (2001) (p. 93); Nutaphand (1990) (p. 50); Schaffer (sic) (1991) (pp. 60-61); Steiof et al. (1991) (p. 69); Welch (1980) (p. 116); Welch et al. (1990) (p. 151); and Wuster (sic) et al. (1997) (p. 132). Listing the works done by Thai authors is of special importance, since these references, often in Thai language, are regularly overlooked by Occidental researchers. Some references are wrongly indicated in the main text: "Gunther (sic) (1961)" on p. 91; "Inger and Elbel (1977)" on p. 92 (Inger and Colwell, 1977); Manthey and Grossmann "(1977)" on p. 55 (1997); Taylor and Elbel "(1950)" on p. 25 (1958). The literature section is largely incomplete. One would have hoped to find a complete list of the numerous herpetological publications of the three authors, but, as two examples among many others, the intensive surveys of the second and third authors (Chan-ard 1996; Chan-ard et al. 2002) in Hala-Bala Wildlife Sanctuary, an area of great zoogeographical importance, or the first record of the Anguidae from Thailand (Nabhitabhata 1987) are absent.

Many of the undocumented species records concern species of difficult identification, or outside of their previously known range, thus with a special zoogeographical or conservation importance. In some cases new taxa could be involved, and the availability of internationally available voucher specimens is crucial. The high proportion of species partly or entirely recorded on the basis of observations made by the authors of the checklist gives, on the one hand, an idea of the huge field experience of the three authors, and on the other hand it stresses the importance of publishing detailed accounts of herpetological collections, in order to firmly document the listing of taxa. Also, it gives an idea of the richness of the mostly unpublished collections of the Thai National Science Museum, on which many records are based, as stressed by the authors in the compilers' note. This museum houses the most

important collection of reptiles in Thailand, more significant than those of Chulalongkorn University and the Queen Saovabah Memorial Institute of the Thai Red Cross in Bangkok.

The present checklist, in spite of the shortcomings listed above, is a very useful work that serves as a perfect companion to the field guide on frogs by Chan-ard (2003) and to the book on amphibians and reptiles of Thailand and Peninsular Malaysia by Chan-ard et al. (1999). Moreover, This checklist, available at the Thai National Science Museum in Pathum Thani and at the OEPP in Bangkok, has an unequaled advantage over all other herpetological books on Thailand: it is free. Although this checklist is a welcome addition to published material on the herpetofauna of Thailand, an updated second edition with more emphasis on voucher specimens and on the source literature would be desirable. Thai amphibian and reptile faunas are far from being adequately known, in spite of the extensive series of investigations made by both Western and Thai herpetologists. A work like this distributional checklist is the right way to present an overview of the Thai fauna, from which taxonomic and biogeographical data can be easily derived. Pending the eventual availability of a more carefully prepared, updated second edition, we highly recommend the prompt acquisition of the present list by all herpetologists and biologists working on the fauna of southeast Asia.

Neotropical rainforests are home to an incredible diversity of amphibians and reptiles, and the taxonomy and systematics of tropical species is becoming clearer, especially with the advent of molecular techniques. However, basic natural history data are still lacking for most Neotropical species, even relatively common ones, due to their generally low abundance and the difficulties associated with studying vertebrates in the tropics. In the field of herpetology, William E. Duellman has devoted a large portion of his career to studying the diversity and natural history of the Neotropical herpetofauna. His latest book, *Cusco Amazónico: The Lives of Amphibians and Reptiles in an Amazonian Rainforest*, is the culmination of decades of work, both in the field and laboratory, on an assemblage of Peruvian herpetofauna. His study site, Cusco Amazónico (now Reserva Amazónica), is located in southeastern Peru along the Madre de Díos River near the Peruvian-Bolivian border. Reserva Amazónica has been highlighted for its high herpetofaunal diversity (e.g., Doan and Arizábal 2002), and Duellman's recent work describes in wonderful detail the natural history of this area, including the geography, topography, weather patterns, vegetation, and of course, the amphibians and reptiles.

Cusco Amazónico is divided into five distinct sections that together encompass the abiotic factors affecting the herpetofauna, community aspects of the herpetofauna, and descriptions with ecological data for each species occurring at the site. The first section includes the introduction, which provides background on the study area and describes the methodology used in data collection. The next section describes the vegetation and physical characteristics of the environment in a very readable (even for a herpetologist) and comprehensive manner. The work of other researchers on the abiotic characteristics of the site complements the amphibian and reptile data, resulting in a comprehensive description of the Reserva Amazónica site rarely seen in the herpetological literature. The third section presents a site-specific summary of the general natural history, species diversity, abundance, and biomass of the herpetofauna. These summaries are incredibly interesting, and give an accurate picture of the overall dynamics of the site. Finally, the last two sections, one for amphibians and one for reptiles, provide thorough dichotomous keys and detailed data for all species recorded from the site or expected to occur at the site based on nearby collection records. Each species account includes nomenclature, morphological characteristics, occurrence, reproduction, and diet information recorded primarily from Reserva Amazónica and supplemented by other literature, which helps to yield a very detailed literature cited section that highlights the herpetology of the Amazon basin as a whole. Helpful attributes of the amphibian section include descriptions of most tadpoles and sonograms of the advertisement calls of many frog species, most of which were previously undescribed.

Two sets of color plates are provided for visual reference, one for amphibians and the other for reptiles. In general, the photography is of good to excellent quality; however, some pictures are dark or out-of-focus, especially those of the rarer species. In many cases where great variation in morphology exists, several photos are included, making the plates more useful for identification purposes. However, in the case of *Oxyrhopus melanogenys*, Duellman notes that this snake has a unique color morph at Cusco Amazónico (page 379); a photograph of a more typical color morph would be helpful for comparative purposes, but noting this in the text provides the reader with a citation to investigate this further.

One obvious benefit of the dichotomous keys is that they are printed in both English and Spanish. This greatly increases the usefulness of the keys and ensures that Peruvians and other Latin American researchers can also take advantage of this work. We visited Reserva Amazónica in late 2004 through early 2005, and had the opportunity to use the keys in a field setting. There are a paucity of works dealing with both reptiles and amphibians from this region, and Duellman's keys are the most comprehensive published to date. In general, the keys were as descriptive and comprehensive as available data allow, although we found a few mistakes, particularly in the reptile key. For example, *Oxyrhopus melanogenys* was identified as *Clelia clelia* using the dichotomous key. Although the two species have similar dorsal scalation and juvenile patterns, after consulting Dixon and Soini (1977), we determined that this was in error. When working with such diversity, and sometimes with very few specimens, mistakes are to be expected and otherwise seemed minimal throughout the book. In fact, just having this material on reptiles and amphibians available in one edition is a huge benefit to neotropical ecologists working in the field.

In particular, we wish to highlight the Epilogue, which relates the field experiences of a biologist at Reserva Amazónica. The interesting twist is that the setting is in a futuristic time period when technology and rainforest knowledge are more advanced. This portion of the book adds a touch of mystery and fantasy to what neotropical fieldwork may be in the future, but we will stop our summary here to prevent spoiling the ending…

For those seriously interested in tropical areas, or areas with high herpetofaunal diversity, this book is a must-have for your collection. *Cusco Amazónico* is the most comprehensive book published on South American herpetofauna to date, displacing

Duellman's (1978) sought-after classic *The Biology of an Equatorial Herpetofauna in Amazonian Ecuador* for this honor. Indeed, this book is rivaled among other volumes on Neotropical amphibians and reptiles only by Jay Savage's *The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, Between Two Seas*. Duellman has set the standard for tropical works extremely high, and those looking to publish a work encompassing amphibians and reptiles residing in the tropics will have a difficult time matching the quality of this book.

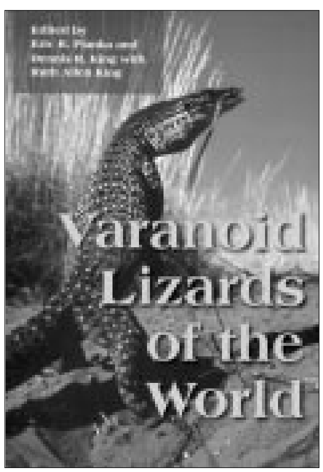
e-mail: vze3vhpv@horizon.net



Monitor lizards and their close relatives have always been a source of interest and fascination among herpetologists and laymen alike. Despite this, until the 1980s general works on varanids were largely limited to those by Mertens (1942a; 1942b; 1942c) for the living species and Fejérváry (1918; 1935) for the extinct taxa. Recently, interest in these lizards has undergone a renaissance with the publication of important volumes devoted to individual taxa, for example: Auffenberg (1981; 1988: 1994), Lenz (1995), and Murphy et al. (2002), as well as general works and symposia, such as: Böhme and Horn (1991), Bennett (1998), Horn and Böhme (1999), and Green and King (1999), and books on varanid paleontology (Molnar 2004). This brief listing does not even begin to account for the enormous wealth of current publications focused on the husbandry of these forms. This new book, edited by Pianka, King, and King, which purports to be a "comprehensive account of virtually everything important that is known about monitor lizards and their allies," is divided into three major sections. The first is focused largely on phylogeny and biogeography, the second and longest is committed to species by species descriptions, and the third discusses the evolution of body size and its importance to reproduction and also examines captive care.

In their introduction Eric Pianka and Dennis King briefly explain that their goal was to compile a single volume reference work about monitor lizards and their allies that touches not only on the systematics of individual species, but also examines their collective biogeography, paleontology, and other important features of their biology. A significant discussion of the paleontology of varanoids by Australian paleoherpetologist Ralph Molnar follows the introductory chapter and occupies 58 pages of this 602-page book. It is the most detailed and up-to-date paleontological review of the group and it also contains a very useful annotated inventory of terrestrial fossil varanoids, updating that of Estes (1983).

There are occasional confusing or erroneous statements in Molnar's review. For example, he notes that the oldest "necrosaur" traces back to the Albian of Utah (Early Cretaceous, about 112-99 million years mya). This can only be the fossil originally described by Cifelli and Nydam in 1995. However, this fossil was later shown by Nydam (2000) to be that of *Primaderma*, which is a monstersaurian not a "necrosaur." Molnar at first refers to *Primaderma* as the oldest land-dwelling platynotan. Later when he discusses monstersaurs in detail, Molnar claims that members of this taxon date back to at least the Late Cretaceous, and that the oldest forms were found in Asia. However, a mere paragraph afterward, Molnar states: "*Primaderma nessovi* is the oldest known monstersaur…its remains were found in the [Early Cretaceous] Cedar Mountain Formation of Central Utah" (page 28). Unfortunate oversights such as this should not have escaped the editors.

The first section of the book concludes with two relatively brief chapters. One, by Pianka and Molnar, is concerned with the biogeography and phylogeny of varanoids generally, although its focus is on the genus *Varanus*. The final chapter in the first section, contributed by Jennings and Pianka, summarizes hypotheses about the tempo and timing for the radiation of Australian monitor species. Their analysis suggests that Australian goannas have undergone repeated and episodic speciation, that the increasing aridity of Australia during the later Tertiary apparently helped drive this diversification and radiation, and that the Australian varanid radiations appear to parallel those of pygopods.

In Part II, the individual species accounts are broken up into four sub-groupings: African varanid species, Asian varanid species, Australian varanid species, and other varanoids. Each subsection contains its own bibliography, and virtually all species descriptions contain all or most of the following subdivisions: nomenclature, geographic distribution, fossil record, diagnostic characteristics, description, size, habitat and natural history, reproduction, movement, population genetics, physiology, fat bodies, testicular cycles, and parasites. Range maps varying in their level of detail are also usually included. Some species acounts are supplemented by tables summarizing morphometric, physiological, or breeding data, or graphs, such as that showing the relation-

ship between body mass and snout-vent length in *Varanus gouldii*. Nearly all species accounts provide a black and white photo above the text for each description, along with duplicate, but separately organized color print, showing a typical representative, usually an adult. These photographs vary in quality, size, and detail.

The African varanid section had a wide range of authors and, as with all the other sections, the amount of detail varied from species to species. All known African species (*Varanus albigularis*, *V. exanthematicus*, *V. griseus*, *V. niloticus*, *V. ornatus*) and the relatively recently described Middle Eastern *V. yemenensis* (Böhme et al. 1987, 1989 [**note**: these two citations are incorrectly listed in the book's bibliography and are corrected here]) are discussed. The account by Michael Stanner describing the desert monitor, *Varanus griseus*, consumes the greatest percentage of this section, about 45%, but fails to resolve whether or not this species is actually venomous as some earlier reports claimed (Ballard and Antonio 2001; Sopiev et al. 1987).

The Asian monitor section describes 23 species, with that for *Varanus salvator* split into two separate segments: one devoted to the nominate form and the other to the various subspecies. It is heavily dominated by German authors and, therefore, many of the species descriptions include diagnostic characters containing references to hemipeneal (and sometimes hemiclitoral) characters that are derived from Böhme (1988). Unfortunately, no general discussion of the specialized terms regarding these important genital characters is provided in this volume and the book's glossary also lacks any definitions to assist unfamiliar readers. Considering that these and many other authors place great significance on these morphological characters to differentiate many varanid species, this deficiency must be corrected in any future editions to ensure comprehensiveness.

In the Asian monitor section several individual species members of the so-called "*Varanus indicus* group" are described separately from the nominate taxon and similar partitioning was also made for members of the "*V. prasinus* group" (which in this volume includes: *V. kordensis*, and *V. macraei*; but not *V. beccari*, and *V. bogerti*). None of the Asian monitor chapters are as detailed as that for *V. griseus*, however, the two segments concerned with *V. salvator* and its subspecies, when combined, come close. The others, all succinct reviews, average about four or five pages each.

The section on Australian monitors has the greatest number of authors and, not surprisingly, the majority are Australians (the one dealing with *V. keithhornei* was even contributed by "Croc Hunter" Steve Irwin). One significant difference between this section and those for the African and Asian monitors is that each Australian species contains a list of specimens in the major Australian museum collections. Many of these specimen lists appear quite exhaustive and all are potentially very useful to any varanid researcher doing work on these species. Unlike for the previous two sections, I could not detect any missing or incorrectly cited references, but similar to these earlier sections, the amount of detail provided for any given Australian species varies. Generally, these descriptions were all concise and averaged somewhere between six and ten pages.

The "Other Varanoids" section contains accounts for *Lanthanotus*, both living species of *Heloderma*, and the Late Cretaceous monstersaur, *Estesia mongoliensis*. *Estesia*, which did not merit a color photo, although a black and white print of the skull leads the chapter, is the only fossil taxon treated in its own individual segment (about two pages) despite the fact it was discussed earlier in Molnar's chapter. Not even the gigantic Australian varanid, *Varanus priscus* [*Megalania prisca*] warranted its own chapter, although this latter species went extinct much more recently in the Pleistocene. All subspecies for *Heloderma* are discussed within the chapters about the two species and their range maps also include subspecies information (both chapters are by *Heloderma* expert, Daniel Beck). Eric Pianka's short chapter on *Lanthanotus* is notable for demonstrating how little is known about this important taxon, particularly concerning its diet and times of activity, as well as reproductive, thermoregulatory, and foraging behaviors.

The book concludes with a two-chapter section. The first, by Pianka, draws an important relationship between body size and reproductive tactics, and basically argues that body size influences reproduction more strongly than phylogeny, particularly: egg mass, clutch size, clutch mass, neonate snout-vent length, and neonate body mass. Pianka also notes that clutch sizes for larger species are normally smaller than those produced by the smaller species and that maternal snout-vent length is a more potent influence on clutch size within a given species than between any two species. The final chapter, by Hans-Georg Horn, examines the captive care of monitors with an eye toward biological, technical, and legal difficulties, and he discusses many relevant issues including: difficulties providing the proper diets, distinguishing males from females, the problems involved with distinguishing between two species showing very similar appearance, problems involving the proper lighting and construction of enclosures, and the effects of various laws, including CITES legislation, on the captive conservation of monitors.

This book will likely be an important single-volume source about varanoid lizards for some time to come. Despite some mostly minor editorial oversights, including those mentioned above, some of which may have resulted from the sudden and unfortunate death of Dennis King during the production of this volume, I believe this book to be a welcome and important addition to the library of any herpetologist. Its importance lies not only in what information it manages to include within its covers, but also in its indication of the significant work still remaining for the more complete understanding and conservation of these important reptiles.

For more than a century, warning coloration and mimicry have fascinated evolutionary biologists and natural historians. In fact, these phenomena helped convince late 19th Century biologists of the power of natural selection.

During the 20th Century, studies of mimicry were common; but reptiles and amphibians were bit players in these studies. A few species were notable exceptions, of course (e.g., coral snakes, egg-eating snakes; reviewed in Pough 1994); but these involved one herp mimicking another. Cases of a herp mimicking an invertebrate are rare (Autumn and Han 1989; Gans 1987; Parker and Pianka 1974; Vitt 1992) and often anecdotal.

In 1977 we proposed that a ground-dwelling lizard in the Kalahari Desert mimicked a beetle (Huey and Pianka 1977). The possibility that a lizard could mimic a beetle must have seemed ludicrous to many, and no doubt some of our colleagues wondered whether we'd spent too much time out in the Kalahari sun. Our evidence was circumstantial; but we were convinced that this was mimicry, and that it involved both color and locomotor behavior.

The model is the juvenile lacertid lizard, *Heliobolus lugubris*, and the mimic is a carabid beetle, *Anthia* spp. Adult *H. lugubris* are sand colored and reasonably cryptic, but juveniles are decidedly conspicuous against the red Kalahari sand. Juveniles have jet-black bodies, with broken white stripes—only their tails are sand colored (Fig. 1). No other lacertid in the Kalahari changes color so dramatically during ontogeny. Nor does any other lacertid of which we are aware.

Both juvenile and adult *H. lugubris* are wide foragers (Huey and Pianka 1981), but they differ strikingly in the way they move. Adults move like normal lacertids (with lateral undulations), but juveniles often move stiff legged, with their backs arched and their tails pressed to the ground (Fig. 1). When the juveniles 'metamorphose' to the adult coloration, they switch from arch-walking to a normal walking style. Juvenile *H. lugubris* are the only lizards known to use arch-walking.

We didn't do a formal phylogenetic analysis, but we realized that two unique features of the juveniles (coloration, arch walking) must be evolutionarily derived and thus called for explanation. When we looked around the Kalahari, we soon noticed carabid beetles (*Anthia*). These beetles are black-and-white, a classic aposematic pattern, and often abundant. Locals refer to them as "oogpisters" (which translates euphemistically as "eye squirter"), because these beetles squirt from their abdomen a noxious mixture of formic acid, tiglic acid, and other compounds (Scott et al. 1975). As far as we were aware, no vertebrate predator ate these noxious beetles.

To us the observed patterns strongly suggested that the beetles were noxious models and that juvenile *H. lugubris* (approximately the same size as the beetles) were Batesian mimics, involving both color and movement. We noted that juveniles of this species had a

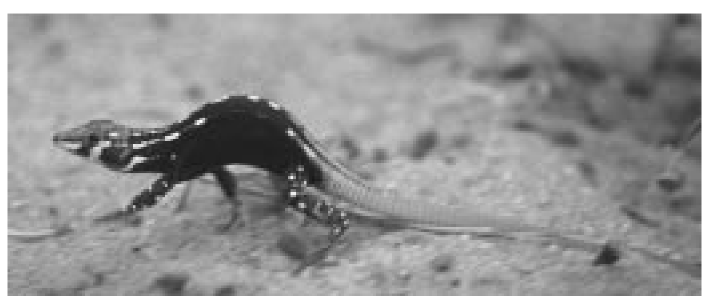

Fig. 1. An arch-walking juvenile *Heliobolus lugubris* (photograph courtesy of A. Schmidt).

low tail-break frequency relative to other juvenile lacertids in the Kalahari, and we interpreted this as evidence of the efficacy of the mimetic resemblance (but see Schoener 1979).

In the late 1990s we began to hear rumors that a German graduate student (Almuth Schmidt) was studying this mimicry complex for her thesis. She has published a few papers on this over the years, but has now synthesized her work in a well-illustrated book. Naturally, we were excited to see her book, to find out how well our ideas stood up, and to learn what new evidence she had uncovered.

Her book is largely in German (a language that has sadly decayed from our brains during ontogeny). Fortunately, all of the table and figure legends are in both English and in German; and the book has a 3-1/2 page summary in English. So the essence of her study is accessible even to an English-restricted audience.

Schmidt worked mainly in two nature reserves in the Limpopo Province of South Africa, rather than in the Kalahari. She presents a diverse set of studies involving careful observations as well as clever experiments. Her studies solidly reinforce the idea of mimicry. Here is a small sample of the kinds of evidence she has garnered:

1) The geographic range of the lizards overlaps with that of abundant carabid beetles (a dozen species of *Thermophilum* and three species of *Anthia*), which serve as models.

2) As juvenile lizards grow, their color and patterns shifts progressively, matching the color of size-matched species of beetles!

3) In staged encounters with beetles, most predators (birds, mammals, monitor lizards) consistently avoided the beetle after being sprayed only once. Thus beetles are indeed strongly noxious, and seemingly unforgettable.

4) Arch-walking juveniles were avoided 100% of the time by visually hunting snakes, but were invariably attacked by the same snakes if they moved normally. Thus arch walking is highly effective against visual predators. (Note: it was against us, too! More than once we briefly confused juvenile lizards for beetles.)

5) Most remarkably, juveniles change their behavior when encountering different snakes. When they encounter a visual hunter, they either remain immobile or use arch-walking. But, when they encounter a snake that hunts using olfaction, they run away at high speed!

Schmidt's studies are inventive and comprehensive, and she has put together one of the most impressive studies of models and mimics we've seen. Her findings will be of considerable interest not only to herpetologists, but also to any behavioral and evolutionary ecologists interested in predation, aposematic coloration, and mimicry. In particular, her discovery that juveniles modify their evasive behavior in response to different kinds of predators is remarkable and deserves to be widely highlighted.

Acknowledgments.—We thank Almuth Schmidt for permission to publish her photograph of an arch-walking *H. lugubris* and for discussion.

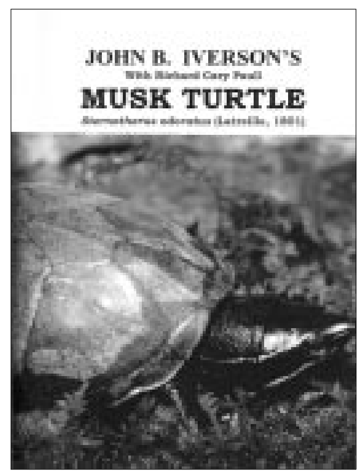
The Musk Turtle Book, by John B. Iverson, with a **Section on Husbandry**, by Richard Cary Paull. 2003. Green Nature Books, P.O. Box 105, Sumterville, Florida 33585, USA. 78 pp. Soft cover. US $29.95 + $3.95 postage. ISBN 1-888089-58-X.

C. KENNETH DODD, JR.
Florida Integrated Science Center, U.S. Geological Survey
7920 N.W. 71st Street, Gainesville, Florida 32653, USA
e-mail: ken_dodd@usgs.gov



Musk turtles are ubiquitous denizens of many types of fresh waters in North America. Populations can be very large, and as such these little turtles are likely important components of aquatic ecosystems as both predators and prey. Anyone who has kept Stinkpots in an aquarium knows that they are quite entertaining and easy to maintain, and it is fortunate that commercial collecting has been restricted in many states because they undoubtedly would be popular in national and international trade. There are a number of musk turtles other than Stinkpots (*S. carinatus, S. depressus, S. minor*), however, and despite this little book's title, these are not covered except exceedingly cursorily in Paull's 5 page section on "Other Musk Turtles."

The book (really a booklet) consists of 40 pages of large bold text by Iverson on the natural history of Stinkpots, 9 pages on husbandry and other musk turtles by Paull, 4 pages of biography (including pictures of the Iverson family and Paull with his granddaughter), and 19 pages of literature cited (with references to early 2003). Only a bare minimum of information on Stinkpot morphology, physiology, or factors other than those relating to natural his-

tory, are included. The book appears to be printed on high quality vellum without using any special publishing program, which in turn makes photographs reproduce very poorly (almost black in some cases) and allows text to be seen through the page. The booklet is paper bound, with a clear front page protector over a color photograph of *Sternotherus odoratus*. The cover provides one version of the title, whereas page 3 has a completely different version (I have shortened both to avoid excessive and confusing verbiage). Maps are identical to those in Iverson (1992), except for a very poor map on page 12 depicting localities for *S. odoratus*. Photos include pictures of turtles and habitats, with some photos taking entire pages.

I almost don't know where to begin, for I consider John Iverson to be one of the most respected turtle scientists active today. There is probably no one who knows more about "little brown turtles" than he does, so my impressions of the booklet become all the more difficult to convey. Iverson reviews the literature on the life history and ecology of Stinkpots quite thoroughly and in great detail, although he adds no new insights or data. I could not find any missing studies of note; if a reader wants facts on natural history, they are here. However, the sheer volume of the literature makes the litany of facts difficult to assimilate, as the reader is embalmed in statement after statement, for example, of "(so and so) reported (x to y) eggs in (wherever)." Simply putting more of this repetitive information (e.g. growth increments, nesting dates, incubation duration) in tables would have helped. Iverson also makes little attempt to put studies of Stinkpots in context with other chelonians, except when they are included with his meta-studies, such as on biomass or survivorship. This is not a book to read, but one that could be consulted for raw information.

A few things need clarification. I presume Iverson means latitudinally rather than altitudinally when discussing reproductive cycles (page 24); if *S. odoratus* is diurnal, as suggested, why does mating and nesting often occur at night (pages 27 and 28); variable sex ratios may not need a complex explanation (pages 36–37) since stochastic variation may occur for a variety of reasons in any one year (in other words, turtle biologists focus too much weight on results from short-term studies of sex ratios, rather than on the long-term population structure); turtles do not hibernate (a physiological ecology term involving endotherms), but become dormant.

I don't have any idea of whom the intended audience of the book might be. All the Stinkpot facts are beyond the interests of most herpetoculturists and amateur naturalists, and the fairly uninformative section on husbandry would insult most turtle aquarists (Paull takes much space talking about tortoises, for some reason). One cannot read this booklet because of its non-literary style, and the price is completely outrageous; I can't imagine herpetologists paying > $30 for this booklet rather than consulting Ernst et al. (1994) and the recent published literature. The poor quality of reproduction, the frequent editorial mistakes (scientific names not italicized, occasional use of English metrics, the heading 'Activity Patern' misspelled), the out-of-place folksy comments by Paull (page 32: "the musk turtle enjoys diving almost as much as boys do on a hot day"), the lack of attention to nomenclature (Stinkpot versus the all-inclusive 'musk turtle'), and the gushy biographies are overwhelming.

The authors could have collaborated to produce a valuable reference, even if privately published (Green Nature Books is Paull's personal publishing outlet), by using a good publishing program, by taking the time to edit the text for style, by opting for consistency in style between authors, and by using paper compatible with photographs. What were the authors thinking?

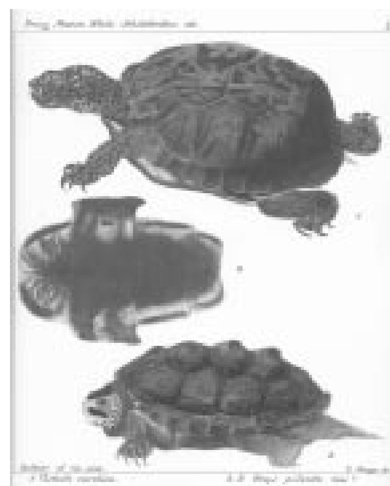
KRAIG ADLER
Department of Neurobiology and Behavior, Cornell University
Seeley G. Mudd Hall, Ithaca, New York 14853–2702, USA
e-mail: kka4@cornell.edu



In 1832, Prince Alexander Philipp Maximilian of the German principality of Wied-Neuwied – former major general in the Prussian army during the Napoleonic wars and veteran explorer of Brazil – embarked on his second and last great expedition, at the age of 50. Together with his Swiss artist, Karl Bodmer, and a team of five assistants, Maximilian traveled by means of small boats over nearly 2700 miles from Saint Louis, Missouri, to Fort McKenzie (near present-day Great Falls, Montana), along the then-treacherous Missouri River. Besides his other credentials, Maximilian was a naturalist and ethnologist, trained by Johann Blumenbach, and he sought to explore what was then "Indian country" beyond the border states of Missouri and Illinois. He was the first trained scientist to do so and his book, "Reise in das innere Nord-Amerika . . . in den Jahren 1832 bis 1834" (published 1839–1841), records his ethnological observations with notes on natural history including herpetology.

Maximilian's definitive scientific report on the amphibians and reptiles – the book reviewed here – was published much later, in

1865, only two years before his death. At that time it was the only extensive account covering the herpetofauna of central North America, thus filling the enormous gap between the region east of the Mississippi River that had been monographed by Holbrook in his two editions of "North American Herpetology" and the various reports on the herpetology of the Pacific Coast based primarily on foreign naval explorations (Russian, French, and British). Maximilian's book is comprehensive, covering 48 species (16 amphibians, 32 reptiles) with detailed descriptions of adults and (where available) juveniles, their colors in life, dimensions, and including extensive natural history notes. It is the fundamental first summary of the herpetology of the Great Plains and also includes Maximilian's observations made along the Ohio River (especially in Pennsylvania and southern Indiana) before he began his ascent of the Missouri.

As such, this book is a classic work that richly deserved reprinting, especially since original copies nowadays fetch prices of US$2000 and more. A reprint of this book is thus welcome, but this is no ordinary reprint. To the contrary, the seven beautifully drafted and accurate plates (five of them depict turtles, the other two the large aquatic salamanders *Cryptobranchus* and *Necturus* plus details of some snake heads; five plates are foldouts) were all originally drawn by Bodmer and are handcolored, both in the original and in this reprint. The latter is a remarkable achievement, given the difficulty to match the originals, and this represents the only herpetological work on North American herpetology with handcolored plates that has been issued in more than a century! These were faithfully colored by Lara Carroll. Copies of the book are available in two states: (1) exquisitely bound with leather spine, raised bands, and marbled paper covers, and (2) unbound, so that the purchaser can have the volume bound to a particular style. The volume is quarto in format, measuring 9 3/4 x 12 1/4 inches (25 x 31 cm).

As with the plates, the text is an exact facsimile of the original in every detail. The rear side of the title page, which is blank in the original, has the only new text added to the reprint. Here, the publisher gives details of the reproduction; it notes the copy number in the limited edition of only 100, and is individually signed by the publisher and colorist. The text and plates are printed on 100% cotton, mould-made, acid-free paper, a distinct improvement over the original in which the paper is routinely browned with age and often foxed due to its poor quality. The only other change from the original is that the final two pages (the errata and an explanation of the plates) are combined on a single leaf in the reprint.

Compared to reprints of classical herpetological works issued by various commercial firms in Europe, South Africa, Japan, and Australia, and including those by the SSAR over the past 45 years, this reprint surpasses them all in the standard of production. It meets the highest criteria and is of a quality of materials and appearance that Prince Maximilian's classic work deserved to have had in 1865!

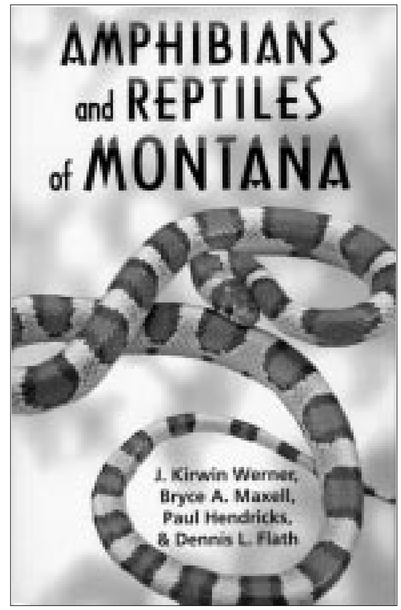
Amphibians and Reptiles of Montana, by J. Kirwin Werner, Bryce A. Maxell, Paul Hendricks, and Dennis L. Flath. 2004. Mountain Press Publishing Company, P.O. Box 239, Missoula, Montana, USA. xii + 262 pp. Softcover. US $20.00. ISBN 0-87842-500-4.

NOAH J. ANDERSON
Department of Biological Sciences, Idaho State University
Pocatello, Idaho 83209-8007, USA
e-mail: andenoah@isu.edu



Two-hundred years have elapsed since the first formal scientific survey of Montana's biota; since that time, 31 species of amphibians and reptiles have been documented from the state. *Amphibians and Reptiles of Montana* summarizes the state of knowledge on the distribution, natural history and conservation status of Montana's herpetofauna. As a state field guide, this book has a large niche to fill; only a handful of recent, comprehensive summaries on amphibians and reptiles exist for the upper Great Plains (Hammerson 1999; Jundt 2000; Russell and Bauer 2000) and surrounding areas (Koch and Peterson 1995; Oldfield and Moriarty 1994; St. John 2002).

The introduction starts with "A Brief History of Herpetology in Montana." This section begins with a short discussion on the role of herpetofauna in the culture of Native Americans of Montana. From there the authors overview a rough chronology of the various and often famous naturalists who studied in Montana, starting with Meriwether Lewis and William Clark's explorations of 1804–1806 to Edward Drinker Cope in the 1860's to present day efforts of herpetologists. Overall, this section is lucid and interesting, but very brief at slightly over eight pages long.

In the "Biology of Amphibians and Reptiles" the authors discuss biological phenomena such as ectothermy, diversity, metamorphosis, food sources, predator relationships, diseases and deformities. The review is accurate and accessible to laypeople. "The Montana Landscape: Habitats for Herpetofauna" covers Montana's spectacular landscape features, from the alpine tundra and boreal forest of the Rocky Mountains, to the five major river systems, and the moonscapes of southeastern Montana's badlands. "Observing Amphibians and Reptiles in the Field" covers the basic steps in observing, capturing and handling reptiles and amphibians. The authors emphasize a conservation ethic in observing and collecting while recognizing the potential role of public reporting

of reptile and amphibian observations. In the "Conservation and Management" section the authors detail conservation concerns, both abroad and within the state.

The majority of the book is composed of species accounts for the 31 amphibians and reptiles found within the state and the six amphibians and reptiles that are of questionable occurrence. Each account includes sections on distribution, notes on identification, taxonomy, habitat/behavior, reproduction/development, remarks and scientific name etymology. The taxonomy is up-to-date and follows SSAR approved lists (Crother 2000). The distribution maps include a full range map and statewide dot locality map (which combines observations and museum vouchers). The species accounts are generously illustrated (most have at least four color photographs), which document color variants, various life stages and natural behaviors. The information in the accounts is accurate but little of it appears to be derived from data on Montana's amphibians and reptiles.

An "Identification Guide" overviews the diagnostic characteristics of adult, larval stages and eggs of all amphibians and reptiles (reptile eggs are not included) in Montana. The guide is well illustrated with color photographs and black and white drawings for each species/stage. This helpful feature ensures that readers will not have to flip back and forth from the species accounts to the keys while attempting to identify an animal. While not a formal dichotomous key, the identification guide should prove useful for anyone to make a solid identification of a reptile or amphibian in hand. I worked through the keys for several species and did not find any mistakes.

The book finishes with several appendices, which include a table of species by eco-region, reproductive characteristics of amphibians and reptiles, contact information for various agencies, an observation report form and a snakebite action sheet. In the tables of the reproductive characteristics, the authors give an impressive summary on the reproductive biology of reptiles and amphibians found in Montana. However, the tables suffer significantly by the complete lack of citations. The book wraps up with a glossary of terms used in the book, an index and a state checklist. The bibliography deserves special mention because it is a "selected bibliography"; this is particularly frustrating, as this belies the fact that the book is well researched at over 500 references consulted.

The front cover includes a county map of Montana and the back cover has a printed ruler. The book is fairly sturdy and appears to be up to the rigors of fieldwork. Finally, a state field guide that was meant to be brought into the field!

I noted very few errors in the text itself; more significant were the photographs that were out of context (e.g., dead animals posed as live and aquatic larvae on land; pgs. 9, 59, 64, 107, 175). For example, the description of handling a snapping turtle (p. 106) states not to handle large animals by the tail, whereas the picture on the opposing page shows someone carrying an adult snapping turtle by the tail. More importantly, I found the nearly complete lack of citations to be the most significant omission of the book. Presumably, the authors did this to keep the text readable for lay-people, however a compromise could have been reached if they simply included significant references at the end of each species account (e.g., Russell and Bauer 2000). Fortunately, all the references are included in a separate publication (Maxell et al. 2003), but will only be accessible those willing to track down that publication.

Overall, Werner et al. have done a fine job on Montana's state field guide. *Amphibians and Reptiles of Montana* should be a handy reference for lay-people, educators, students, state and federal wildlife biologists, and anyone with an interest in the natural history of Montana's biota. Herpetologists will also want to pick up the companion publication (Maxell, et al. 2003) which more formally summarizes the distribution, history, museum records, dichotomous keys and complete bibliography. Between these two books (Maxell et al. 2003, Werner et al. 2004), the authors have created an excellent reference set on Montana's amphibians and reptiles that compares favorably with many state herpetological guides in print. Anyone interested in reptiles and amphibians of the west and great plains regions should have this book on their shelf.

Symposium on Conservation of Mesoamerican Herpetofauna

A symposium entitled "Conservation and Herpetology: The Middle American Connection" will be held 31 March and 1–2 April 2006 at the Kendall Campus of Miami-Dade Community College in Miami, Florida, USA. Symposium participants will address topics of the significance and conservation status of the megadiverse Mesoamerican herpetofauna (Mexico through Panama). The keynote speaker with be the noted conservation biologist Simon N. Stuart. A peer-reviewed symposium volume is planned, based on the presentations at the symposium and invited papers. Information is available from Larry David Wilson, organizer, by e-mail at: lwilson@mdc.edu.

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.html>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR Treasurer (Dr. Theodora Pinou; contact information below) or from the SSAR web page (http://www.ssarherps.org/pdf/Adrates.pdf).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Dr. Theodora Pinou, SSAR Treasurer, Western Connecticut State University, Department of Biological & Environmental Sciences, 181 White Street, Danbury, Connecticut 06810, USA.

Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below), regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 760	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com.

Herpetological Review

Volume 36, Number 3
September 2005

FIG. 1. Male *Sistrurus catenatus catenatus* from the Upper Wapsipinicon River, Bremer County, Iowa, USA, engaged in combat.

op. cit.), several similarities exist, specifically, 1) displaying with the anterior portion of the body elevated in an S-shape and laterally swaying to gain superior position, 2) topping—one male gains the superior position and pushes the anterior portion of the other male to the ground in a quick movement, and 3) continuous contact of the posterior portion of the body. One notable difference was observed; an exaggerated posture of bending over backwards was observed on several occasions during this encounter. In male combat it is predicted that the larger male will typically prevail, which might result in increased reproductive opportunities for the larger male (Schuett and Gillingham 1989. Amphibia-Reptilia 10:243–266; Shine 1994, *op. cit.*). The apparent winner of this bout was M2, who was longer than M1, but weighed less.

I thank Robb Goldsberry, Wendy VanDeWalle, Stacey Carlson, John Goedeken, and James L. Christiansen for assistance. The Iowa Department of Natural Resources and the U.S. Fish and Wildlife Service provided funding.

Submitted by **TERRY J. VANDEWALLE,** Earth Tech, Inc., 501 Sycamore Street, Suite 222, Waterloo, Iowa 50703, USA; e-mail: terry.vandewalle@earthtech.com.

TROPIDOPHIS WRIGHTI (NCN). **SIZE RECORD.** A male *Tropidophis wrighti* collected at Vista Alegre, Santiago de Cuba City, Santiago de Cuba Province in 1946 was maintained in captivity and fed with *Anolis* for more than two years (it died on 20 June 1949). The specimen (CTR 2; "Charles T. Ramsden" Collection deposited at Instituto de Ecología y Sistemática, Havana City Province, Cuba) measures 488 mm snout–vent length, 64 mm tail length, 14.5 mm head length, and 8.4 mm head width, and has 23 dorsal scale rows at midbody, 202 ventrals, 37 subcaudals, four spot rows, 28–31 body spots and 4-4 subcaudal spots. The previously reported maximum length for *T. wrighti* is 330 mm SVL (Hedges 2002. Bull. Nat. Hist. Mus. Lond. [Zool.] 68[2]:83–91). With this size record, *T. wrighti* becomes the second largest species of *Tropidophis* in Cuba, surpassed only by *T. melanurus*.

We thank Elier Fonseca, Lourdes Rodríguez Schettino, and Luis F. de Armas for suggestions on the manuscript.

Submitted by **MICHEL DOMÍNGUEZ** (e-mail: micdom2002@yahoo.es), **LUIS V. MORENO**, División de Colecciones Zoológicas, Instituto de Ecología y Sistemática, Carretera de Varona km 3, Capdevila, Boyeros, A.P. 8029, C.P. 10800, Ciudad de La Habana, Cuba; and **MICHEL SÁNCHEZ**, IPA "Villena-Revolución," Ave. Van Troi y Final, Reparto General Peraza, Boyeros, Ciudad de La Habana, Cuba.

GEOGRAPHIC DISTRIBUTION

Instructions for contributors to Geographic Distribution appear in Volume 36, Number 1 (March 2005). Please note that the responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extension reports unless a thorough literature review has been completed.

CAUDATA

AMBYSTOMA MACULATUM (Spotted Salamander). USA: TENNESSEE: CARROLL CO.: Tennessee National Guard Milan Reserve, just SE of Halls Branch ca. 0.4 miles SE of Headquarters on TN Hwy 104 (35°54'13"N,88°39'20"W). 20 November 2004. John Maxwell. Austin Peay State University Museum of Zoology, APSU 6298 (color photo). Verified by A. Floyd Scott. One adult found under rotting log in shallow depression. New county record that augments the scant amount of existing data on the distribution of the species in west Tennessee (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. [Hard copy and Internet versions, the latter of which includes links to information on amphibians in Tennessee having appeared since 1996], http://www.apsu.edu/amatlas/, accessed 10 February 2005).

Submitted by **JOHN MAXWELL**, 5581 Cole Street, McKenzie, Tennessee 38201, USA; e-mail: redhawk_202@hotmail.com.

AMBYSTOMA TALPOIDEUM (Mole Salamander). USA: VIRGINIA: CAMPBELL Co: Brookneal, man-made pond 300 m SE of State Rd. 643, ca. 2 km from intersection of State Rd. 643 and U.S. Highway 501 (37°07'09.5"N, 78°59'02.4"W), 10 May 2004. Paul R. Moosman, Jr., Deanne L. Moosman, and Jeremy C. Pillow. Verified by Craig Guyer. Photographs deposited in the Alabama Herp. Atlas Project at Auburn University (AUM-AHAP-0785a and AUM-AHAP-0785b). Larvae and metamorphs were observed in an ephemeral pond surrounded by pasture. Only 15 other breeding sites have been documented in Virginia (Hayslett 2003. M.S. Thesis, Longwood College).

Submitted by **PAUL R. MOOSMAN, JR.**, Department of Biological Sciences, 331 Funchess Hall, Auburn University, Alabama 36849-5414, USA (e-mail: moosmpr@auburn.edu); **DEANNE L. MOOSMAN**, Alabama Cooperative Fish and Wildlife Research Unit, 103 Swingle Hall, Auburn University, Alabama 36849-5419, USA (e-mail: swartdl@auburn.edu); and **JEREMY C. PILLOW**, 7308 Lewis Ford Rd., Gladys, Virginia 24554, USA.

SIREN INTERMEDIA (Lesser Siren). USA: ILLINOIS: JERSEY Co.: Stump Lake, wetland S of IL Hwy. 100, ca. 1.0 km S from Stump Lake Road to unnamed road; from unnamed road ca. 2.1 km W (39°00'42"N; 090°33'51"W). Larva ca. 4 cm in TL at time of capture. Red stripe present on mouth and jaw. Late May, early June of 2002, Emily Dustman. INHS-2004.02 (Photo taken after 1 year in captivity). Verified by J. K. Tucker. New county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 282 pp.). MADISON Co.: Horseshoe Lake, backwater adjacent to IL Hwy. 111, ca. 1.3 km S of dam (38°41'02"N; 090°04'10"W). Multiple larvae ranged from 5–7.5 cm TL at time of collection. Yellow stripes present on mouth and jaw. 27 June 2004. Emily Dustman. INHS-2004.24. Augments an Academy of Natural Sciences (Philadelphia) specimen collected by Cope (no date) as the only Madison County records (C. A. Phillips, pers. comm.).

Submitted by **EMILY DUSTMAN,** 82 Eastmoor Drive, Wood River, Illinois 62095, USA; e-mail: LmnLime03@yahoo.com.

ANURA

BARYCHOLOS TERNETZI (Chimbo Frog). BRAZIL: MARANHÂO: Municipality of Balsas (07°43'36"S, 46°17'15" W). 9 September 2000. L. Barreto and C. Arzabe. Museu Nacional de Rio de Janeiro, Brazil (MNRJ 36480–36481). Verified by J. P. Pombal Jr. Species previously known from Minas Gerais, Goiás, Mato Grosso, and Tocantins States, and the Distrito Federal, Brazil. First state record, extends known distribution 405 km NE from the closest previous record Porto Nacional (10°42'29"S, 48°25' 02" W), Tocantins State (Caramaschi and Pombal Jr. 2001. J. Herpetol. 35:357–360).

Submitted by **LARISSA BARRETO**, Departamento de Oceanografia e Limnologia, Universidade Federal do Maranhão, Campus do Bacanga, Av. dos Portugueses s/n, 65080-040, São Luís MA, Brazil (e-mail: lara@elo.com.br); and **CRISTINA ARZABE**, Embrapa Meio-Norte, Setor de Recursos Naturais e Desenvolvimento Sustentável, Av. Duque de Caxias N. 5650, B. Buenos Aires, 64006-220, Teresina PI, Brazil (e-mail: arzabe@cpamn.embrap.br).

BUFO HENSELI. BRAZIL: Paraná: Municipality of São João do Triunfo (25°34'18"S. 50°05'56"W), 780 m elev. 25 October 2003. A. M. X. Lima. C. F. B. Haddad collection, deposited in Departamento de Zoologia, Universidade Estadual Paulista, Rio Claro, São Paulo, Brazil (CFBH 7566). Verified by C. F. B. Haddad. Captured by pitfall trap. Previously recorded from the states of Rio Grande do Sul e Santa Catarina (Baldissera-Jr et al. 2004. Arquivos do Museu Nacional, Rio de Janeiro 62[3]:255–282). First state record, extends known distribution ca. 250 km to NE.

Submitted by **ANDRÉ MAGNANI XAVIER DE LIMA** (e-mail: andremxlima@uol.com.br), **RENATO GARCIA RODRIGUES, SHANNA BITTENCOURT, LUIZ HENRIQUE CONDRATI**, Laboratório de Inventário Florestal, Universidade Federal do Paraná, CEP 80210-170, Curitiba, Paraná, Brazil; and **REGINALDO ASSÊNCIO MACHADO**, Faculdade de Ciências Médicas de Cacoal, CEP 78976-005, Cacoal-Rondônia, Brazil.

BUFO PUNCTATUS (Red-spotted Toad). USA: NEW MEXICO: TORRENCE Co.: Abo ruins unit, Salinas Pueblo Missions National Monument, UTM (NAD27) 13S, 373436 E, 3812380 N, ca. 1829 m elev. 18 May 2001. Trevor B. Persons and Shawn C. Knox. MSB/USGS Biological Survey Collection, BS/FC 7868. Verified by Cindy Ramotnik. New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. University of New Mexico Press, Albuquerque, 431 pp.).

Submitted by **TREVOR B. PERSONS** (e-mail: Trevor.Persons@nau.edu) and **ERIKA M. NOWAK** (e-mail: Erika.Nowak@nau.edu), USGS Southwest Biological Science Center, Colorado Plateau Research Station, Box 5614, Northern Arizona University, Flagstaff, Arizona 86011-5614, USA.

BUFO WOODHOUSII (Woodhouse's Toad). USA: TEXAS: KLEBERG Co.: Padre Island, Road P22, 6 rd mi S of State Route 361 (27.5316°N, 97.25802°W, ± 5 m, NAD27 CONUS). 15 Oct 2004. Rachel E. Seabury. Verified by Travis J. LaDuc. TNHC 63255 (TNHC-FS 91). 92 mm SVL; adult female collected AOR at 2000 h. This is the first specimen reported for this county and is the northernmost record for the south Texas range of *B. woodhousii* (Dixon 2000. Amphibians and Reptiles of Texas, 2nd edition, Texas A&M University Press, 421 pp.). This record partially fills the gap between the south Texas and central Texas populations, with the hiatus in the coastal distribution still including the mainland of Kleberg County as well as the next two counties to the north, Nueces and San Patricio (Dixon 2000, *op. cit.*). Dixon (2000, *op. cit.*) suggested that *B. woodhousii* was extirpated from south Texas, and although this might be true for the mainland, this record suggests that individuals persist on Padre Island.

Submitted by **RACHEL E. SEABURY**, Section of Integrative Biology, One University Station (C0930), University of Texas, Austin, Texas 78712, USA; **DAVID W. HALL**, and **GREGORY B. PAULY,** Section of Integrative Biology and Texas Memorial Museum, One University Station (C0930), University of Texas, Austin, Texas 78712, USA.

COCHRANELLA DAIDALEA (Alban Cochran Frog). COLOMBIA, DEPARTAMENTO DEL CESAR. MUNICIPIO GONZÁLEZ: Vereda San Cayetano (12°25'30.1"N, 73°24'3.4'"W), ca. 1600 m

elev. 10 Sept 2004. Museo de Herpetología Universidad de Antioquia, Medellín, Colombia (MHUA 3271–3272). 13 Sept 2004 (MHUA 3273–3278). J. M. Daza-R. Verified by J. D. Lynch. Species endemic to Colombia and has been known only from Cundinamarca and Santander departments (Ruiz-Carranza and Lynch 1991. Lozania 59:1–8). First department record, extends known distribution to northern part of Cordillera Oriental, ca. 138 km NW from Municipio Tona, the northernmost locality previously mentioned (Ruiz-Carranza and Lynch, *op. cit.*).

Submitted by **JUAN MANUEL DAZA-R.** (e-mail: juandaza35@hotmail.com) and **LUCAS S. BARRIENTOS**, Grupo Herpetológico de Antioquia, Instituto de Biología, Bloque 7-121, Universidad de Antioquia, A.A. 1226, Medellín, Colombia.

ELEUTHERODACTYLUS CAVERNIBARDUS (NCN). BRAZIL: AMAZONAS: Municipality of Barcelos, Serra do Tapirapecó, base camp at southern versant of Pico Tamacuari (1°12'30"N, 64°45'13"W, 930–1200 m elev.). 6–7 May 2004. P. M. S. Nunes. Museu Nacional, Rio de Janeiro, Brazil (MNRJ 36183–36186). Collected at night on the ground in forest bordering a river. Verified by C. A. G. Cruz. Previously known only from the type locality, "from the north base of Pico Tamacuari, 1160–1200 m elevation, Sierra Tapirapecó, Amazonas, Venezuela (1°13'N, 64°42'W)" (Myers and Donnelly 1997. Amer. Mus. Nov. 3213:1–71; Frost 2004. Amphibian Species of the World: An online reference. Version 3.0. 22 August 2004. http://research.amnh.org./herpetology/amphibia/index.html). First documented record for Brazil.

Submitted by **ULISSES CARAMASCHI** and **HELIANNE DE NIEMEYER**, Departamento de Vertebrados, Museu Nacional/UFRJ, Quinta da Boa Vista, 20940-040 Rio de Janeiro, RJ, Brazil; e-mail: ulisses@acd.ufrj.br.

ELEUTHERODACTYLUS CYSTIGNATHOIDES (Rio Grande Chirping Frog). USA: TEXAS: Brazoria Co.: City of Alvin, 2216 FM 517. 18 March 2004. Michael James McCoid. Texas Natural History Collection 63681. Verified by Travis LaDuc. First record for this county but the species has been recorded in neighboring counties (Frost 2004. Amphibian Species of the World: an Online Reference. Version 3.0 [22 August, 2004]. http://research.amnh.org/herpetology/amphibia/index.php. American Museum of Natural History, New York). The specimen was collected at 0645 h from beneath discarded cardboard. There had been rain the previous evening. Many Rio Grande Chirping Frogs had been heard calling from areas all around this house suggesting the population was fairly large and has been established for some time.

Submitted by **MICHAEL JAMES McCOID**, Department of Pathology, University of Texas Medical Branch, 301 University Blvd., Galveston, Texas 77555-0609, USA; e-mail: mjmccoid@utmb.edu.

HYLA MICROCEPHALA (Yellow Treefrog). HONDURAS: ISLAS DE LA BAHIA: Isla De Utila: 1.3 km from Utila on the road to Pumpkin Hill Beach (16°06'76"N, 86°53'29"W). 17 September 2001. Alexander Gutsche. Museo Natural de Historia, Tegucigalpa (UNAH 4355, 4356). Verified by James R. McCranie. First record for Isla de Utila (Köhler 1998. Senck. Biol. 77:139–145). Both specimens were captured within a temporarily flooded wetland, covered with grasses and cattails.

Submitted by **ALEXANDER GUTSCHE**, Humboldt-Universität zu Berlin, Inst. für Biologie, Abt. Sinnesbiologie, Invalidenstr. 43, D-10115 Berlin, Germany; e-mail: alexander-gutsche@web.de.

HYLA NANA (Dwarf Treefrog). ARGENTINA: TUCUMÁN: DEPARTAMENTO MONTEROS: Capitán Cáceres (27°12'S, 65°38'W). 3 March 2005. M. L. Ponssa. Verified by G. Scrocchi. Herpetological Collection Fundación Miguel Lillo, San Miguel de Tucumán, Argentina (FML 16064–70, adult males calling on low vegetation of temporal ponds; 16071 adult female). The species range includes diverse areas of Brazil, Paraguay, Bolivia, Uruguay, and the Argentine provinces of Salta, Formosa, Chaco, Santa Fe, Misiones, Corrientes, Entre Ríos, and Buenos Aires (Lavilla et al. 2000. Categorización de los Anfibios y Reptiles de la República Argentina. Asociación Herpetológica Argentina, pp. 11–34). First province record and the southernmost in the western range; extends the known distribution ca. 550 km S from its closest record, Aguas Blancas in Salta (Langone and Basso 1987. Com. Zool. Mus. Hist. Nat. Montevideo 11[164]:1–17). Historically, this area consistsed of montane forests (Andean Yungas), but at present is strongly disturbed by crops and human settlements.

Submitted by **MARÍA LAURA PONSSA** and **ESTEBAN LAVILLA,** Instituto de Herpetología, Fundación Miguel Lillo, Miguel Lillo 251, San Miguel de Tucumán, 4000, Argentina; e-mail: mlponssa@arnet.com.ar.

HYOPHRYNE HISTRIO (Bahia Yellow Frog). BRAZIL: BAHIA: Itambé Municipality, União farm (15°16'S, 40°27'W). 19 August 2003. A. J. S. Argôlo. Museu de Zoologia da Universidade Estadual de Santa Cruz, Ilhéus (MZUESC 3771). Verified by E. F. Spirandeli Cruz. The species was known only from the Ilhéus Municipality (Frost 1985. Amphibians Species of the World. A Taxonomic and Geographical Reference. Allen Press, Inc., Lawrence, Kansas. vi +732 pp.) and was recently rediscovered at the Una Municipality 60 km S of Ilhéus (Dixo 2004. Phyllomedusa 3:77–79). Both localities lie in the domain of the Atlantic rainforest. This record extends range ca. 150 km W from Una and also points out mesophytic forest as habitat of the species.

Submitted by **ANTÔNIO JORGE SUZART ARGÔLO**, Universidade Estadual de Santa Cruz – UESC, Km 16 Rodovia Ilhéus-Itabuna, CEP 45650-000, Ilhéus, Bahia, Brazil; e-mail: lachesis@uesc.br.

MELANOPHRYNISCUS PACHYRHYNUS. URUGUAY: DEPARTAMENTO DE CERRO LARGO: Cuchilla de Mangrullo (32°14'S; 53°51'W; 265 m elev.). 16 May 2004. C. Borteiro, S. Borteiro, F. Gutiérrez, F. Kolenc, and M. Tedros. Verified by M. Di-Bernardo and R. Maneyro. Vertebrates Zoology Collection, Facultad de Ciencias, Universidad de la República, Montevideo, Uruguay (ZVCB 11097–11098). Previously known only from type locality, São Lourenço do Sul, Rio Grande do Sul, Brazil (Caramaschi and Cruz 2002. Arquivos do Museu Nacional, Rio de Janeiro 60:303–314). First country record, extends the known range of the species ca. 300 km SW.

PHYSALAEMUS AGUIRREI (Linhares Dwarf Frog). BRAZIL: MINAS GERAIS: MUNICIPALITY OF NANUQUE (17°50'S, 40°21'W, 104 m elev.). 4–7 June and 2–5 September 2002. R. R. Carvalho-Jr. Museu de Ciências Naturais, Pontifícia Universidade Católica de Minas Gerais, Belo Horizonte, Minas Gerais (MCNAM 2915, 3016–34). Collected using pitfall traps on the leaf litter at forest fragment within Atlantic domains. Verified by U. Caramaschi and C. A. G. Cruz. Published distribution for the species is the type locality, Refúgio Sooretama, Linhares, Espírito Santo, Brazil (Frost 2000. Amphibian Species of the World. An Online Reference. http://research.amnh.org/herpetology/amphibia/) and Caravelas, Bahia, Brazil (Sluys 1998. Herpetol. Rev. 29:49). First state record, represents the westernmost record for the species and extends the known distribution ca. 120 km W from Caravelas (Sluys 1998, *op. cit.*).

Submitted by **RONALD REZENDE DE CARVALHO JÚNIOR** and **LUCIANA BARRETO NASCIMENTO**, Pontifícia Universidade Católica de Minas Gerais, Av. Dom José Gaspar 290, Coração Eucarístico, 30536-610, Belo Horizonte, MG, Brazil; e-mail: rcjunior.bh@terra.com.br.

PHYSALAEMUS MAXIMUS (NCN). BRAZIL: MINAS GERAIS: MUNICIPALITY OF OURO PRETO (20°29'S, 43°35'W, 1248 m elev.). November 2004. D. P. B. da Costa, B. de Assis, and P. H. Bernardo. Laboratório de Zoologia dos Vertebrados, Universidade Federal de Ouro Preto, Ouro Preto, Minas Gerais, Brazil (LZV 301A and 330A). Verified by R. N. Feio. Previously known only from the type locality in the mountains of Serra do Brigadeiro (20°42'S, 42°29'W, 1375 m elev.), Municipality of Arapongas, Minas Gerais (Feio et al. 1999. Copeia 1999:141–145). Present record extends known distribution ca. 120 km SW from the type locality.

TESTUDINES

ACTINEMYS MARMORATA (Pacific Pond Turtle). MEXICO: BAJA CALIFORNIA NORTE: Rio Santo Tomas, 16 air km E Santo Tomas near Rancho Las Aguillas (31.54998°N, 116.22561°W), 400 m elev., 26 March 2004. Los Angeles County Museum of Natural History voucher photographs (LACM PC 1401–1402). Observed by Robert Lovich, Barry Downer, and Clark Mahrdt. Photos verified by Jeffrey E. Lovich. This species occurs

in several Pacific river drainages west of the Sierra Juarez and Sierra San Pedro Martir peninsular range, south to Arroyo Grande, east of El Rosario in northwestern Baja California (Grismer 2002. Amphibians and Reptiles of Baja California including its Pacific Islands and the Islands in the Sea of Cortés. University of California Press, Berkeley and Los Angeles, California; Grismer and McGuire 1993. Bull. South. California Acad. Sci. 92:2–24). One adult male *Actinemys marmorata* was observed in riparian habitat in a boulder-strewn pool ca. 1–2 m in depth. The Río Santo Tomas individual represents a new inland record for this drainage located ca. 43 km upstream from vouchers collected in 1952 and 1957 in the estuary of the Rio Santo Tomas (UAZ 22057 and LACM 105323, respectively), and confirms the persistence of this population in a rapidly developing agricultural region. Anecdotal reports for this species in Upper Rio Santo Tomas occur in Roberts (1981. California Riparian Systems Conference, UC Davis, Sept. 17–19; 1982. Proc. Desert Tortoise Council 1982 Symp., pp. 154–161).

LACERTILIA

ANOLIS CAROLINENSIS (Green Anole). USA: HAWAI'I: Honolulu Co.: O'ahu, Moku o Lo'e (Coconut Island) in Kane'ohe Bay, 21°26.2'N, 157°47.6'W, 11 March 2004. J. Panza and R. Powell. Milwaukee Public Museum (MPM-P 720). Verified by A. C. Echternacht. First record for the island (F. Kraus, in litt., 29 March 2005). This population had become established since March 2002, when extensive surveys of the island's lizards were conducted by RP.

Submitted by **JANELLE M. PANSZA** and **ROBERT POWELL**, Department of Biology, Avila University, Kansas City, Missouri 64145, USA; e-mail: powellr@mail.avila.edu.

ANOLIS SAGREI (Cuban Brown Anole). USA: HAWAI'I: Honolulu Co.: O'ahu, Moku o Lo'e (Coconut Island) in Kane'ohe Bay, 21°26.2'N, 157°47.6'W, 6 March 2004. R. Powell. Milwaukee Public Museum (MPM-P 719). Verified by A. C. Echternacht. First record for the island (F. Kraus, in litt., 29 March 2005). This population had become established since March 2002, when extensive surveys of the island's lizards were conducted by RP.

Submitted by **ROBERT POWELL** and **JANELLE M. PANSZA**, Department of Biology, Avila University, Kansas City, Missouri 64145, USA; e-mail: powellr@mail.avila.edu.

CNEMIDOPHORUS ABAETENSIS (Sand Dune Lizard). BRAZIL: BAHIA: Municipality of Mata de São João, sand dune (12°25'S, 37°54W). July 2003. 5 m elev. M. A. de Freitas and W. Guerreiro. Laboratório de Animais Peçonhentos e Herpetologia da Universidade Estadual de Feira de Santana, Feira de Santana, Bahia, Brazil (LAPH/UEFS 439). Municipality of Entre Rios, sand dune (11°55'S, 38°04'W), July 2004. 5 m elev. M. A. de Freitas and T. F. S.Silva (LAPH-UEFS 440). All specimens were found in "restinga" habitats and verified by E. Dias. The species was known only from type locality at Parque do Abaeté, Salvador, Bahia (Dias et al. 2002. Copeia 2002:1070–1072). These new records extend the species range ca. 100 km N from the type locality.

Submitted by **MARCO ANTONIO DE FREITAS**, **THAIS FIGUEIREDO SANTOS SILVA**, and **WAGNER GUERREIRO**, Rua Sotero Gomes n 05, Vila de Abrantes. CEP 42-800-000 Camaçaré, Bahia, Brazil; e-mail: philodryas@hotmail.com.

HEMIDACTYLUS TURCICUS (Mediterranean House Gecko). ARIZONA: Yuma Co.: Yuma, Dorn St. and 18th Place, 14 Sept 2002 (LACM 153071); La Paz Co.: Parker, 14th and Reata St., 9 Aug 2003 (LACM 155077). Mohave Co.: Lake Havasu City, Beachcomber RV Resort, 8 Aug 2002 (LACM 153041); Willow Valley, 0.25 mi. W of Hwy. 95, 7 July 2000 (LACM 152942). All specimens verified by Kent Beaman, Natural History Museum of Los Angeles County. A museum search revealed an earlier unpublished record from La Paz County, consisting of two collected at Ehrenberg in 1988 (UAZ 47784–85), verified by George Bradley, University of Arizona.

The introduced Mediterranean House Gecko was first documented for Arizona in the mid 1960s and early 1970s at Tucson and Phoenix (Robinson and Romack 1973. J. Herpetol. 7:311–312). A literature search revealed one published record for western Arizona. Stebbins (2003. A Field Guide to Western Reptiles and Amphibians, 533 pp. Houghton Mifflin Co., New York) lists this species at Yuma. It is not clear if a voucher specimen exists to support this record (R. C. Stebbins, pers. comm.). Our voucher supports the earlier Yuma County record. Our findings shows that *H. turcicus* is now widely established along the lower Colorado River in southwestern Arizona.

HEMIDACTYLUS TURCICUS (Mediterranean House Gecko). USA: LOUISIANA: Caddo Parish: Shreveport: 500 W. 61st Street. 23 October 1976, Mattson. Verified by Beth E. Leuck. Louisiana State University in Shreveport Museum of Life Sciences (LSUS 3998–99). This species was listed by Hardy (1979. Bull. Mus. Life Sci., LSUS [2]:1–11) as occurring in Caddo Parish, Louisiana, but no specific locality was given. Additional records obtained subsequent to 1976 include LSUS 4000–1, 4255–67, 4275–6, 4394–403, 5243, 5330, 7349, 7377, 8120–1, 8231, 8235, 8715, 8772–3, and 8925. This collection consists of 42 specimens collected over 28 years from 15 localities and 15 collection dates (7 Jan–29 Nov). Localities prior to 1989 (31 specimens) were collected at or near grocery warehouses in Shreveport. Subsequent localities include eight specimens that are from residential neighborhoods throughout Shreveport and Caddo Parish. This is the first specific locality record for this species in Caddo Parish.

Submitted by **LAURENCE M. HARDY** (e-mail: lhardy@pilot.lsus.edu), **AMANDA C. CRNKOVIC** (e-mail: acrkovi@pilot.lsus.edu), and **LARRY R. RAYMOND** (e-mail: lraymond@caddo.org), Museum of Life Sciences, Louisiana State University in Shreveport, One University Place, Shreveport, Louisiana 71115-2399, USA.

OPHISAURUS ATTENUATUS (Slender Glass Lizard).USA: TEXAS: MILLS CO.: 12 May 2001. DOR Hwy 84 ca. 3 miles E of FM 2005. University of Texas at Arlington Collection of Vertebrates (UTA R-52936). Verified by Eric N. Smith. New County Record (Dixon 2000. Amphibians and Reptiles of Texas, A&M University Press. 421 pp.).

Submitted by **CARL J. FRANKLIN**, Amphibian and Reptile Diversity Research Center, The University of Texas at Arlington Department of Biology. Arlington, Texas 76019, USA; e-mail: Franklin@uta.edu.

PODARCIS MURALIS (Common Wall Lizard). USA: INDIANA: CLARK CO.: (38.2769, 85.7644): Clarksville. *Podarcis muralis* was first observed by ZW on river bank stabilizations adjacent to The Falls of The Ohio State Park Educational Center on 25 June 2004. An adult male was subsequently captured on 8 July 2004. This specimen was sent to Russell Burke at Hofstra University (Hempstead, New York) for identification and tissue collection then deposited at the Chicago Field Museum of Natural History (FMNH 266504). Nate Engbrecht collected additional tail tissue from two subadults on 25 September, 2004 and released the specimens immediately at their point of capture. GD observed two juveniles which hatched in 2004, judging from their size, and one adult on 30 September 2004. A molecular analysis of tissue samples was performed at the Laboratory for Molecular Systematics of the Natural History Museum in Vienna, Austria whose aid we gratefully acknowledge. The Indiana specimens proved to be genetically identical in their mitochondrial cytochrome b sequence to specimens from Cincinnati (Schweiger and Deichsel 2003. Herpetol. Rev. 34:166–167, Gene Bank accession no. AY194855). The method described in Schweiger and Deichsel (2003, *op. cit.*), was used for analysis of the Clarksville specimens as well. The reference sequences most similar to the sequences of the Clarksville and Cincinnati samples were from individuals collected in a region between the Tyrolian Inn Valley and the southern border of the Alps near Lake Garda in Italy. This similarity confirms the origin alleged by Deichsel and Gist (2001. Herpetol. Rev. 34:230–232), Lake Garda. However, because a revision of the systematics of *P. muralis* is still in progress, the subspecific status of the Clarksville and Cincinnati specimens remains unresolved. We conclude that a reproducing colony of *P. muralis* established itself in Clarksville, Indiana. It is unknown how the lizards got there from Cincinnati. Release cannot be excluded, but rafting on flotsam is possible as well. Prokoph (2003. Die Eidechse 14[2]:61–63, English translation at www.lacerta.de) documents rafting of members of a European *Lacerta agilis* colony formerly living on a jetty during the flood event of the Elbe river near Meissen, Germany in August 2002. Flotsam deposits between Cincinnati and Clarksville will be searched for *Podarcis* in an effort to support the rafting hypothesis. The Clarksville population represents the first documented observations of *P. muralis* in Indiana.

Miller Drive, Bloomington, Indiana 47401, USA (e-mail: zwalker@dnr.IN.gov); and **GUNTRAM DEICHSEL**, Friedr.-Ebert-Str., 62, Biberach a.d.Riss, Germany D-88400 (e-mail Guntram.Deichsel@bc.boehringer-ingelheim.com).

PTYCHOGLOSSUS BREVIFRONTALIS (Boulenger's Large-scaled Lizard). BRAZIL: AMAZONAS: Municipality of Manaus, Reserva Florestal Aldolpho Ducke (02°55'S, 59°59'W). 27 April 2004–14 August 2004. M. G. M. Pinto and W. E. Quatman. Verified by T. C. S. Ávila-Pires. Coleção de Anfíbios e Répteis do Instituto Nacional de Pesquisas da Amazônia (INPA-H 12477–481), collected in pitfall traps in a "terra firme" forest. Previously known from the state of Rondônia in Brazil (Vanzolini 1986. Levantamento herpetológico da área do estado de Rondônia sob a influência da rodovia BR 364. Programa Polonoroeste, subprograma Ecologia Animal, Relatório de Pesquisa nº 1:1–50. MCT/CNPq), from Surinam-Brazil border (Hoogmoed 1973. Biogeographica 4:1–419) and from Ecuador, Bolivia, and Peru (Avila-Pires 1995. Lizards of Brazilian Amazonia. Zool. Verh. Leiden. 299:1–706). First state record, fills the gap in the distribution and indicates that this species ranges throughout the Amazon Basin. Extends known range ca. 670 km from the nearest northern record at Acarai Mountains, Surinam-Brazil border (Hoogmoed 1973, *op. cit*); ca. 900 km from the nearest southern record in the state of Rondônia, Brazil (Vanzolini 1986, *op.cit.*), and ca. 1100 km from the nearest western record in Valpés state, Colombia (Ayala 1986. Caldasia 15[71–75]:555–575).

Submitted by **MARIA GORETTI M. PINTO** and **WILLIAM E. QUATMAN**, Coordenação de Pesquisas em Ecologia, Instituto Nacional de Pesquisas da Amazônia –INPA, CP. 478, CEP 69.011-970, Manaus, AM, Brazil; e-mail: mgorettimp@yahoo.com.br.

SERPENTES

CORALLUS ANNULATUS (Annulated Tree Boa). COLOMBIA: DEPARTAMENTO DE ANTIOQUIA: Municipio Yarumal, Corregimiento El Cedro, Vereda Medialuna (7°12'21"N, 75°19'17"W) ca. 610 m. elev. 17 April 1997. J. M. Daza-R. Museo de Herpetología Universidad de Antioquia, Medellín, Colombia (MHUA 14015). Verified by R. W. Henderson. This species is distributed from extreme southeastern Guatemala to Rio San Juan in Colombia (Henderson et al. 2001. Stud. Neotrop. Fauna Environ. 36:39–47). In Colombia this species was reported from Chocoan lowland forests in Municipio Cabeceras near the Rio San Juan and only one record from Municipio Girón, Department of Santander. This is the first record for the Department of Antioquia and the northern part of the Cordillera Central in northwestern of Colombia. Vereda Medialuna is part of the Nechí River Basin that in turn is a tributary of Cauca River near the end of the Cordillera Central and is ca. 382 km NE of Cabeceras (Departamento de Chocó) and ca. 239 km W of Girón (Departamento de Santander). This record fills the distributional hiatus of this species between the Chocoan region and Rio Magdalena Basin and is evidence that the Chocoan biogeographic region extends through the northern part of the Cordillera Central (Hernández-Camacho et al. 1992.

Acta Zool. Mex. Spec. Vol., pp. 175–190).

Submitted by **JUAN MANUEL DAZA-R.**, Museo Herpetológico de Antioquia, Instituto de Biología, Bloque 7-121, Universidad de Antioquia, A.A. 1226, Medellín, Colombia; juandaza35@hotmail.com.

DRYMARCHON CAUDOMACULATUS. VENEZUELA: ZULIA: Municipio Machiques de Perijá, San José de Perijá, Hacienda San Sebastián (9°59'N, 72°24'W). 07 May 2004. E. Infante Rivero and P. Velozo Delgado. Museo de Biología de La Universidad del Zulia, Maracaibo, Venezuela (MBLUZ-R-0835). Verified by M. Natera. *D. caudomaculatus* has been considered an endemic species of the Falcón state in Venezuela, with its distribution restricted to one small area of this state in the northwest of the country (Wüster et al. 2001. Herpetol. J. 11:157–165). This is the first state record for Zulia and the westernmost locality, extending the known distribution ca. 337 km (air line) SW of the nearest locality in Taratara, Falcón state, (Wüster et al., *op. cit.*).

LEPTOTYPHLOPS BRASILIENSIS (Blind Snake). BRAZIL: MINAS GERAIS: Municipality of Três Marias (18°12'00"S, 45°15'00"W). 1987. Museu Nacional, Rio de Janeiro, Brazil (MNRJ 4616, juvenile female 99 mm SVL, 8 mm TL). Verified by R. Fernandes. First state record for the State of Minas Gerais and third known locality, extends the distributional range ca. 680 km S of Barreiras, State of Bahia (Rodrigues and Puorto 1994. J. Herpetol. 28:393–394). Seventh known specimen, recorded previously from Estação Ecológica Uruçuí-Una, State of Piauí. (Curcio et al., 2002. Phyllomedusa 1[2]:101–104).

Submitted by **ROBERTA R. PINTO, PAULO PASSOS,** and **ULISSES CARAMASCHI**, Museu Nacional, Universidade Federal do Rio de Janeiro, Departamento de Vertebrados, Quinta da Boa Vista, São Cristóvão, Rio de Janeiro, RJ, 20940-040, Brazil; e-mail (RRP): robertarich@mn.ufrj.br.

LEPTOTYPHLOPS UNGUIROSTRIS. PARAGUAY: DEPARTAMENTO BOQUERÓN: Estancia "Toro Mocho" (23°30'S, 60°31'W). 24 October 2003. P. Cacciali and F Brusquetti. Museo Nacional de Historia Natural del Paraguay, San Lorenzo, Paraguay (MNHNP 10625, female, SVL 101 mm, TL 2 mm). Verified by N. Scott. Mentioned previously in Argentina from Río Negro to Salta and Formosa (Kretzschmar 1996. Acta zool. lilloana 43[2]:275–279; Lanari and López 2000. Herpetol. Rev. 31:182); cited from southern Paraguay without specific localities or voucher specimens (Peters and Oerejas Miranda 1970. Catalogue of the Neotropical Squamata: Part I, Snakes. Bull. U.S. Nat. Mus. 297:1–347; Cei 1993. Reptiles del Noroeste, Nordeste y Este de la Argentina. Mus. Reg. Scien. Natur. Torino, Monogr. XIV, Turín, Italy. 949 pp.; McDiarmid et al. 1999. Snake Species of the World. Vol. 1. Herpetol. League. 511 pp.; Leynaud and Bucher 1999. Acad. Nac. Cien. Miscelánea. 98, 46 pp.). Present record confirms the presence of the species in Paraguay, and extends range ca. 192 km SE of Formosa (Lanari and López, *op. cit.*); 346 km E of Finca Pozo Largo (Kretzschmar, *op. cit.*) and 447 km NW of Corrientes (Giraudo 2001. Serpientes de la Selva Paranaense y del Chaco Húmedo. L.O.L.A. Monogr. 17: 285 pp.; Álvarez et al. 2002. Atlas de Anfibios y Reptiles de las Provincias de Corrientes, Corrientes, Chaco y Formosa (Argentina). Fac. Cienc. Exac. Nat. y Agrim., Universidad Nacional del Nordeste. 156 pp).

OPHEODRYS AESTIVUS (Rough Greensnake). USA: KENTUCKY: Mercer Co.: near Shreve, DOR. 13 July 1979. Albert Westerman. Verified by Jeffrey G. Davis. Thomas More College Herpetology Collection (TMC R263). County record (Meade. 1993. Ph.D. Dissertation, University of Southern Mississippi).

Submitted by **MATTHEW C. FERNER**, Skidaway Institute of Oceanography, 10 Ocean Science Circle, Savannah, Georgia 31411, USA; and **JOHN W. FERNER**, Department of Biology, Thomas More College, Crestview Hills, Kentucky 41017, USA (e-mail: john.ferner@thomasmore.edu).

PHALOTRIS NASUTUS. BRAZIL: MATO GROSSO DO SUL: AQUIDAUANA: Rio Negro Farm (19°33.30' S, 56°13.44' W). 10 January 2004. E. Wang and V. L. Ferreira. Verified by F. Franco. Zoology Collection, Laboratório de Zoologia, Campus de Corumbá, Universidade Federal de Mato Grosso do Sul, Corumbá, Mato Grosso do Sul, Brazil (CEUCH 3032). Adults collected in pitfall traps with drift fence in semi-deciduous forest surrounding soda water lake. The species was recorded in Cerrado biome in central Brazil (Distrito Federal, Goiás, Minas Gerais, São Paulo, Mato Grosso and Mato Grosso do Sul states) by Lema (2002. Comun. Mus. Ciênc. tecnol. PUCRS, 15[2]:201–214) and Lema (2003. Comun. Mus. Ciênc. tecnol. PUCRS, 16[1]:17–37), and very likely for Alta Floresta in N Mato Grosso state by Ferrarezzi (1993. Memórias do Instituto Butantan 55[1]:21–38). This record is the second for Mato Grosso do Sul state and extends the known distribution for this species ca. 410 km NW from Xavantina (21°15"S, 52°44"W) (Lema 1999. Herpetol. Rev. 30:175), ca. 420 km SW from Emas National Park region (18°06.53'S, 52°55.20'W), in the state Goiás that bounds the states of Mato Grosso do Sul and Mato Grosso (Valdujo and Nogueira 2001. Herpetol. Rev. 32:129) and ca. 1000 km S of Alta Floresta in Mato Grosso state, if its identification in the last locality is confirmed (Memorias do Instituto Butantan 55[1]:21–38).

Submitted by **VANDA LÚCIA FERREIRA,** Lab. Zoologia, Campus de Corumbá, Universidade Federal de Mato Grosso do Sul, CxP. 252, CEP 79301-970, Corumbá, MS, Brazil (e-mail: vandaf@ceuc.ufms.br); **ELLEN WANG** (e-mail: nyctibeus@yahoo.com), Earthwatch Institute, Rua Doze de Outubro, 2323, 19015-090 Presidente Prudente, SP, Brazil; and **JEFFREY ALAN HIMMELSTEIN** (e-mail: kiantunich@aol.com), Biology Department, William Paterson University, 300 Pompton Road, Wayne, New Jersey 07470, USA.

STEGONOTUS CUCULLATUS (Slatey Grey Snake). AUSTRALIA: QUEENSLAND: Townsville: Mount Stuart Road, Mount Stuart (19°21'19"S, 146°49'01"E). 29 October 2003. Ray Lloyd. Verified by Andrew Amey. Queensland Museum, QMJ81126. Fresh DOR, adult male (SVL 771mm), found in open eucalypt woodland at 2200 h after heavy rains. This represents the southernmost record of the species, extending its range by 35 km from Herveys Range, Townsville, the previous southern limit for the species, from which two specimens (QMJ61798 and QMJ67364) were collected.

Submitted by **DANE TREMBATH**, Applied Ecology Research Group, University of Canberra, Canberra, Australian Capital Territory, Australia 2601 (e-mail: Trembath@aerg.canberra.edu.au); and **RAY LLOYD**, 6 Beach Street, Corinella, Victoria, Australia 3984 (e-mail: Ray.Lloyd@jcu.edu.au).

STENORRHINA FREMINVILLEI COLOMBIA: SUCRE: Municipio de San Marcos, road to "La Mojana," site Cuiva near: 08°39'40"N, 75°08'05"W, near a "Zapal," in the morning, in shrub. Instituto de Investigaciones Biológicas Alexander von Humboldt, Villa de Leyva, Boyacá, Colombia (IAvH 3444). 7 December 1986. A. Fajardo. CHOCÓ: Municipio de Riosucio: Parque Nacional Natural Los Katios, Vereda Peye. February 1976. J. V. Rodríguez and H. Pavas (IAvH 1964); Vereda Tilupo. 5 April 1978. J. V. Rodríguez and H. Pavas (IAvH 1957). Verified by J. M. Renjifo. Previously known from Atlantic versant from the isthmus of Tehuantepec to central Honduras and from Guerrero, Mexico, south to the Meseta Central Occidental of Costa Rica on the Pacific slope. Scattered records also exist in Costa Rica on the Meseta Central Oriental and northeastern Atlantic lowlands near the base of Cordillera Central and the Cordillera of Tilarán (Savage 2002. The Amphibians and Reptiles of Costa Rica: a Herpetofauna Between Two Continents, Between Two Seas. University Chicago Press, Chicago, Illinois. 934 pp.). First record for Colombia (and South America). Southernmost record for the species, extends known distribution about 1000 km S from Cordillera the Tilarán, the closest locality previously mentioned (Savage, *op.cit.*).

Submitted by **EMIL JOSÉ HERNÁNDEZ-RUZ**, Investigador Asociado, Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Apartado aéreo 7495, Bogotá, D.C., Colombia; e-mail: emilhjh@yahoo.com.

STORERIA DEKAYI (Dekay's Brownsnake). USA: KENTUCKY: BRECKINRIDGE CO.: Hwy 259 in Yellow Bank Refuge, DOR. 17 April 1982. Albert Westerman. Verified by Jeffrey G. Davis. Thomas More College Herpetology Collection (TMC R262). County record. Validates a previous county record cited without a voucher specimen by Meade (1993. Ph.D. Dissertation, University of Southern Mississippi).

Submitted by **JOHN W. FERNER** and **AMY WILSON**, Department of Biology, Thomas More College, Crestview Hills, Kentucky 41017, USA; e-mail: john.ferner@thomasmore.edu.

STORERIA DEKAYI WRIGHTORUM (Midland Brownsnake). USA: ARKANSAS: LITTLE RIVER CO: 2.0 km E Ashdown off St. Hwy. 32. 13 November 2004. Z. D. Ramsey. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 28840). Verified by Stanley E. Trauth. New county record completely filling hiatus in extreme southwestern Arkansas (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville. 421 pp.) and near recent record of *S. d. wrightorum* from adjacent Sevier County (Ramsey and McAllister 2004. Herpetol. Rev. 35:193).

Submitted by **ZACHARY D. RAMSEY** and **CHRIS T. McALLISTER,** Department of Biology, Texas A&M University-Texarkana, Texarkana, Texas 75505, USA; e-mail: chris.mcallister@tamut.edu.

Erratum

We mistakenly credited Erik Wild as the photographer of a photo from the SSAR annual meeting that appeared on page 308 of the December 2004 issue of HR (vol. 35, number 4). The image should have been credited to Julian Lee.

and

CÉSAR L. BARRIO-AMORÓS
*Fundación AndígenA. Apartado Postal 210, 5101-A Mérida, Venezuela
e-mail: cesarlba@yahoo.com*

Cojedes state, with a surface area of 14,800 km^2, is situated in the west-central part of Venezuela (northern border with Carabobo state: 10º00'N, upper Tinaquillo River; southern border with Barinas state: 08º35'N; eastern border with Guárico state: 68º00'W; western border with Portuguesa state: 68º50'W). The northwest section is within the Coastal Range, and forms the western limit for some species, such as *Atelopus cruciger* (Rivas 1998), *Hyalinobatrachium antisthenesi, Cochranella revocata* (Señaris and Ayarzagüena 2005) and *Anolis squamulatus* (Rivas and Manzanilla 1999 "2001"). The center and south are part of Los Llanos, supporting such species as *Bufo granulosus*, *Hyla crepitans, Phrynohyas venulosa, Leptodactylus fuscus, Tropidurus hispidus*, *Chironius carinatus*, *Leptodeira annulata*, *Liophis melanotus* (Rivero-Blanco and Dixon 1979).

Two main seasons exist in Cojedes, a wet one, from May to October, and a dry one, from November to April. The lowest elevations of Cojedes (ca. 50 m elev.) are found in the south, along the boundary with Portuguesa (Esteros de Chiriguana). The highest point is the Nirgua Massif, north of "Fila Refilete" (1520 m elev.).

Despite its central location in Venezuela and its proximity to the Venezuelan capital, Caracas, Cojedes is one of the least explored states in Venezuela. Only a few works mention its herpetofauna. Prior to this work only 24 amphibian species had been recorded (Barrio-Amorós 1998; Manzanilla et. al. 2000; Rada 1989–1990; Rivas 1998; Rivas and Manzanilla 1999a, b; Señaris and Ayarzagüena 2005) along with only 10 species of reptiles (Cole et al. 1990; Dixon et al. 1993; Donoso-Barros 1966; Pritchard and Trebbau 1984; Rivas and Fuentes 2000; Rivas and Manzanilla 1999 "2001"; Roze 1966).

In this work we report five amphibians and 33 reptiles new to Cojedes, based mainly on voucher specimens in the Museo de Historia Natural La Salle, Caracas (MHNLS) and Museo de la Estación Biológica de Rancho Grande, Aragua (EBRG). We have also exhaustively reviewed literature pertaining to Cojedes herpetofauna. We followed La Marca (1997) for the taxonomic treatment of reptiles, except for anoline lizards, where we followed Nicholson (2002). We followed Barrio-Amorós (1998) for the taxonomic treatment of amphibians and major bioregions.

ANURA

BUFONIDAE

Bufo humbolti (Sapo Granuloso). Municipio Girardot: Hato Los Caballos, 68 km S of Tinaco, 210 m elev. 25 February 1978. Miguel Lentino and Alfredo Paolillo. Verified by F. Rojas. MHNLS 6978–6979. First state record, 60 km NNE from nearest known locality, Río Guanare, Portuguesa (Barrio-Amorós 1998).

Bufo margaritifer complex. (Sapo Crestado). Municipio San Carlos: Cerro Azul, Fila La Blanquera, 1300 m elev. 25 February 1979. Alfredo Paolillo. Verified by F. Rojas. MHNLS 7493–7494. First state record. This complex is widely distributed in Venezuela and includes several species, with a new taxon recently described as *Bufo sclerocephalus* (Mijares-Urrutia and Arends 2001). In Colombia, at least 13 species are under the name *Bufo typhonius* (Vélez 1995).

HYLIDAE

Flectonotus pygmaeus (Ranita Marsupial Pigmea). Municipio San Carlos: Cerro Azul, Fila La Blanquera 1350 m elev. 03 April 1980. Luis Paéz. Verified by A. Paolillo. MHNLS 8100–8101. First state record. This record is between localities in Carabobo and Falcón states (Barrio-Amorós 1998).

Gastrotheca ovifera (Rana Marsupial Común). Municipio San Carlos: Cerro Azul, Fila La Blanquera, 1350 m elev. 31 March 1980. Alfredo Paolillo. Verified by F. Rojas. MHNLS 8095. First state record. This record is between previously known localities in Carabobo and Yaracuy states (Barrio 1999a).

Gastrotheca walkeri (Rana Marsupial Cornuda). Municipio San Carlos: Cerro Azul, Fila La Blanquera, 1350 m elev. 2 April 1980. Ignacio Agudo. Verified by J. C. Señaris. MHNLS 8106. First state record. This record is between previously known localities in Aragua and Yaracuy states (Barrio 1999b).

LACERTILIA

AMPHISBAENIDAE

Amphisbaena alba (Morrona, Culebra de Dos Cabezas). Municipio San Carlos: San Carlos, campus Cojedes, Fundación La Salle de Ciencias Naturales, 148 m elev. 9 April 1979. Unknown collector. Verified by J. C. Señaris. MHNLS 13828. First state record, ca. 190 km NE of the closest record, La Colonia, Portuguesa (Markezich 2002). This specimen was collected during the day after a heavy rain.

GEKKONIDAE

Gonatodes vittatus (Limpia Casa). Municipio San Carlos: San Carlos, 120–140 m elev. 9 September 1997. Gilson Rivas. Verified by J. C. Señaris. MHNLS 13829, adult male. First state record (Rivero-Blanco 1979). This specimen was collected on a building wall. This species shows a continuous distribution along the coast from Trinidad to Colombia, and although the distribution depicted by Rivero-Blanco (1979) includes a dot in Lara state the specimen is not referenced in the appendix of examined material. Anthropogenic transport might be responsible for the presence of *G. vittatus* in San Carlos. These animals have been seen and collected only in association with buildings. The material used in the construction of these structures is known to come from the coast. Gorzula and Señaris (1998) report a similar case in Venezuelan Guayana. Markezich (2002) reported this species from Portuguesa, without speculating on its origin.

Phyllodactylus ventralis (Tuqueque). Municipio Girardot: Rio Portuguesa, 15 km S El Baul, 90 m elev. 16 January 1966. Jon Bilbao and Carlos Galan. Verified by A. Paolillo. MHNLS 2422, a juvenile. First state record (Dixon and Huey 1970). Extends the range 85 km NW from the nearest locality, Hato Masaguaral (Staton and Dixon 1977). The species is distributed through north-central Venezuela to some localities in the east (Dixon and Huey, *op. cit.*).

Thecadactylus rapicauda (Salamanqueja). Municipio San Carlos: El Candelo, SW de La Sierra, Tucuragua, 640 m elev. 09 April 1979. Daniel Loureiro. Verified by A. Paolillo. MHNLS 7653. First state record. This monoptypic species has a wide distribution in Venezuela, but is apparently absent from the Llanos. This bioregion is occupied by other large geckos (*Phyllodactylus ventralis* and *Hemidactylus palaichthus*). It is very possible that *T. rapicauda* contains more than one species (see Mijares-Urrutia and Arends 2000).

IGUANIDAE

Iguana iguana (Iguana Verde). Municipio Girardot: río Tinaco, 20 km NW El Baul. 06 February 1978. R. Godshalk. EBRG 1078; Municipio Pao de San Juan Bautista: Hato Galeras del Pao, 190 m elev. 24 August 1995. Ramón Rivero. EBRG 3178. All verified by R. Rivero. First state records. This species has a wide distribution in all lowlands of Venezuela, but has few documented records. The Cojedes localities are about 110 km from the closest ones in Guanarito, Portuguesa (Markezich 2002).

POLYCHROTIDAE

Norops auratus (Cotejo). Municipio San Carlos: San Carlos, 120–140 m elev. 11 February 1998. Alejandro Cuesta. Verified by J. C. Señaris. MHNLS 13871. First state record; 150 km NE de Guanare (Markezich 2002). The species is widely distributed north and south of the Orinoco River, in the states of Aragua, Apure, Barinas, Falcón, Guarico, Sucre, Amazonas, and Bolívar (Donoso-Barros 1968; Gorzula and Señaris 1998; Manzanilla et al. 1996; Mijares and Arends 1993; Ramos and Busto 1989–1990).

Norops chrysolepis (Cotejo). Municipio San Carlos: Cerro Azul, Fila La Blanquera, 1350 m elev. 02 April 1980. Reinaldo Correa. Verified by A. Paolillo. MHNLS 8096, adult male. First state record, ca. 200 km NE from Mesa Cavacas, Portuguesa (Markezich 2002). This species is also known in the literature as *Anolis nitens nitens* (see Avila-Pires 1995; Markezich 2002).

TEIIDAE

Ameiva ameiva (Cotejo). Municipio Girardot: Hato la Laguna de Junco km 80 road from Tinaco to El Baul. 18 April 1980. Alfredo Paolillo. Verified by F. Rojas. MHNLS 8421. First state record, ca. 200 km NE from Portuguesa state records (Markezich 2002). Staton and Dixon (1977) refer to specimens from La Guanota (Apure) and Masaguaral (Guarico) 120 and 180 km SE, respectively.

Cnemidophorus lemniscatus complex (Cotejo). Municipio San Carlos: La Sierra, 06 August 1946. Luis Carbonell. Verified by G. Marcuzzi. MHNLS 115. First state record. The species in this complex have a wide distribution in northern South America (Avila-Pires 1995; Donoso-Barros 1966).

Tupinambis teguixin (Mato Pollero). Municipio Pao de San Juan Bautista: Hato Galeras del Pao, 190 m elev. 29 August 1995. Ramón Rivero. Verified by R. Rivero. EBRG 3190. First state record. This is another widely distributed species with few documented records in Venezuela. The locality is ca. 170 km NW from closest records in Portuguesa (Markezich 2002).

TROPIDURIDAE

Tropidurus hispidus (Cotejo). Municipio San Carlos: Hato Itabama, 38 km SW of Las Vegas. 80 m elev. 26 September 1976. Carlos de Lima. Verified by J. C. Señaris. MHNLS 6625–6626, juvenile. First state record, ca. 170 km NE from Fundo Sabana Grande, Portuguesa (Markezich 2002).

SERPENTES
BOIDAE

Corallus ruschenbergerii (Falsa Mapanare, Dormilona). Municipio Girardot: Río Tinaco, Hato San Blas. 03 February 1978. Robert Goshalk. EBRG 1090; Municipio Girardot: Hato Mata Clara, between Hato Piñero and El Baul. M. Gonzalez. 03 April 1998. EBRG 3458. All verified by R. Rivero. These specimens are the first records from the state. Hato Mata Clara is 160 km E from closest record in La Colonia, Portuguesa (Markezich 2002). Henderson (1993) plotted some dots on his map of the species that could lie within Cojedes, but no specimens examined were cited. Cojedes samples are not found in the Henderson (1997) appendix of examined material.

Epicrates maurus (Tornasol). Municipio San Carlos: San Carlos, 120–140 m. 26 June 1985. Pedro Miraval. Verified by J. C. Señaris. MHNLS 13833. First state records, ca. 190 km NE from nearest record in Portugesa (Markezich 2002), and 157 km NW from Hato Masaguaral, Guárico (Staton and Dixon 1977). We consider *E. maurus* a valid species (see Chippaux 1986; Gorzula and Señaris 1998).

COLUBRIDAE

Atractus univittatus. Municipio San Carlos: Potrero Largo, Manrique. 19 April 1979. Verified by Walter Schargel. MHNLS 13834. First state record, ca. 160 km NE from La Colonia, Municipio Guanare (Markezich 2002). This species was previously known only from the Coastal Range and from the foothills of Andean cordillera of Mérida in Portuguesa (Markezich 2002; Roze 1966).

Erythrolampus bizona (Falsa Coral). Municipio San Carlos: San Carlos, Boca Toma. 16 April 1973. José Blondet. Verified by G. Marquez. MHNLS 6058. First state record. This locality is 130 km NE from Mesa de Cavacas, Portuguesa (Markezich 2002), and about 110 km SW from Valencia, Carabobo (Roze 1966).

Helicops angulatus (Mapanare de Agua). Municipio Rómulo Gallegos: Parcelamiento La Blanca, 130 m elev. 1996 (exact date not given). Numa Hurtado. Verified by J. C. Señaris. MHNLS 14580–14581. First state record. This species is widely distributed throughout the Orinoco Basin in Venezuela, from the state of Sucre to the east (Rivas and Oliveros 1997) to Portuguesa in the West (Markezich 2002).

Leptodeira annulata ashmeadii (Falsa Mapanare). Municipio

Girardot: El Baul. 12 September 1995. Fabiola León and Luis Merlo. Verified by J. C. Señaris. MHNLS 13296–13299. First state record. 90 km NW from the nearest locality, Hato Masaguaral (Staton and Dixon 1977). This species is widely distributed in Venezuela (Markezich 2002; Roze 1966). These specimens were found DOR. Staton and Dixon (1977) consider this species ubiquitous in the central llanos.

Leptophis ahaetulla (Lora). Municipio San Carlos: Hato Itabama, 38 km SW of Las Vegas. 80 m elev. 1 August 1976. Alfredo Paolillo. Veified by J. C. Señaris. MHNLS 6446. First state record. Represents a range extension of ca. 150 km NE from Portuguesa (Markezich 2002; Roze 1966). This species is in need of a taxonomic review as some varieties might deserve species status (Markezich 2002; Oliver 1942).

Liophis lineatus (Sabanera). Municipio San Carlos: Hato Itabama, 38 km SW of Las Vegas. 80 m elev. 14 August 1976. Miguel Lentino and Alfredo Paolillo. Verified by F. Rojas. MHNLS 6449. First state record and northern most record for the species in Venezuela, ca. 65 km NE Acarigua, Portuguesa (Michaud and Dixon 1987; Roze 1966), and 148 km NW from Hato Masaguaral, Guárico (Staton and Dixon 1977).

Liophis melanotus melanotus (Sabanera). Municipio San Carlos: Hato Itabama, 38 km SW of Las Vegas. 80 m elev. 3 August 1976. Alfredo Paolillo. Verified by F. Rojas. MHNLS 6457. First state record, ca. 65 km NE Acarigua, Portuguesa (Dixon and Michaud 1992).

Masticophis mentovarius (Conejera, Cazadora). Municipio San Carlos: San Carlos. Francisco Delascio. Verified by A. Paolillo. 24 August 1978. MHNLS 7070. First state record. This species is widely distributed in semi-arid regions and dry forests through northern Venezuela, including Margarita Island, and lowlands of northern Bolívar (Gorzula and Señaris 1998; Hernández and Rada 1992; Roze 1966). Cojedes locality is 67 km SW of Bejuma (Carabobo) and 310 km NW of Espino in Guárico (Roze 1966).

Mastigodryas biffosatus striatus (Tigra). Municipio San Carlos: San Carlos. 23 May 1985. Collector unknown. Verified by J. C. Señaris. MHNLS 13870. First record for Cojedes, and 150 km NE of closest record in Portuguesa (Markezich 2002). This species is distributed through dry regions of northern Venezuela (Roze 1966).

Mastigodryas boddaertii (Cazadora). Municipio San Carlos: carretera Tierra Caliente-La Sierra. 9 October 1975. Wilson Damo. Verified by J. C. Señaris. MHNLS 6359. First state record. This locality is 120 km S of the closest record in Borburata, Carabobo (Hernández and Rada 1993; Roze 1966). The known distribution of this species shows that *M. boddaertii* is the only member of the genus that frequents forests with relatively high humidity.

Oxyrhopus petola (Falsa Coral). Municipio Rómulo Gallegos: Parcelamiento La Blanca, 130 m elev. 1996 (specific data not given). Numa Hurtado. Verified by J. C. Señaris. MHNLS 15129, juvenile. First state record (Roze 1966). This form is not assigned to any described subspecies, as the great variation of color pattern in the same population makes taxonomic resolution difficult (Starace 1998).

Pseudoboa neuwiedii (Coral Macho). Municipio Girardot: El Baul. 12 September 1995. Fabiola León and Luis Merlo. Verified by J. C. Señaris. MHNLS 13301–13302. First state record, 90 km NW from Hato Masaguaral, Guárico (Staton and Dixon 1977), and ca. 200 km NE from closest Portuguesa record (Markezich 2002). These specimens were found DOR.

Sibon nebulata. Municipio San Carlos: San Carlos. 19 April 1979. Verified by L. F. Navarrete. MHNLS 13837–13838. In Venezuela this species is known from the Andes (including the Sierra de Périja), the coastal range (including Margarita island) and southern Venezuela in the state of Bolívar. The species inhabits relatively humid forest and is apparently absent in the dry forest lowland know as los Llanos. These specimens represent a new state record from Cojedes, ca. 60 km E of Agua Blanca and ca. 145 SW from Guarico (see Peters 1960 and Roze 1966 for known Venezuelan records).

Tantilla melanocephala. Municipio San Carlos: Quebrada La Lapentera, Cerro Azul. 2 April 1980. Ignacio Agudo and Alfredo Paolillo. Verified by J. C. Señaris. MHNLS 8107–8110. First state record and first record for the Venezuelan lowlands known as Los Llanos (Wilson and Mena 1980), this site is at 100 km SW from Belén, Carabobo state (Roze 1966) and 150 km NE de Mesa de Cavacas, Portuguesa (Markezich 2002).

Thamnodynastes cf. *pallidus*. Municipio Rómulo Gallegos: Parcelamiento La Blanca, 130 m elev. 1996 (exact date not given). Numa Hurtado. Verified by J. Manzanilla. MHNLS 15130–15131. First state record (Roze 1966). In this genus more than one taxon remains without formal description. We tentatively identify this specimen as *T. pallidus*, as *T. strigilis* is a synonym (Cei et al. 1992).

Xenodon severus (Sapa). Municipio San Carlos: Cerro Azul, Fila La Blanquera, 1350 m elev. 1 April 1980. Reinaldo Correa. Verified by J. C. Señaris. MHNLS 8163, an adult female. First state record ca. 100 km SW from Puerto Cabello, Carabobo (Roze 1966). This locality is the easternmost in the interior Coastal Range. The specimen contains an adult *Bufo margaritifer* in its stomach.

ELAPIDAE

Micrurus isozonus (Coral). Municipio Girardot: carretera El Baul-Hato Piñero. 31 December 1989. Rafael Hoogesteijn. EBRG 2406; Municipio: Tinaco. 05 April 2000. Gilson Rivas. EBRG 3651; Municipio Tinaco: Hato Piñero. No date. John Polisar. EBRG 3662. All verified by R. Rivero. First state records (Roze 1966, 1996). This is another widely distributed species in the Llanos region, with a few documented records. The closest known locality is in Maracay, Aragua, ca.75 km NE (Roze 1966).

VIPERIDAE

Crotalus durissus (Cascabel). Municipio Pao de San Juan Bautista: Laya, Las Minas. 16 December 1999. Ramón Rivero. EBRG 2310; Municipio Girardot: Hato Piñero. No date: John Polisar. EBRG 3661. All verified by R. Rivero. First state records (Vanzolini and Callefo 2002). This species complex is widely distributed in lowlands and uplands throughout Venezuela (Roze 1966). Is likely that the species complex embraces more than one species, and for this reason we do not assign these specimens to any proposed subspecies. In our opinion the subspecies *Crotalus d. cumanensis, C. d. ruruima,* and *C. d. pifanorum* are sufficiently different to be

considered full species. Another endemic Venezuelan species of *Crotalus*, *C. vegrandis*, is considered by some authors as a subspecies of *C. durissus* (McDiarmid et al. 1999).

LEPTOTYPHLOPIDAE

Leptotyphlops albifrons (Cieguita). Municipio Girardot: Hato Piñero, Estación Biológica. 14 November 1996. John Polisar. Verified by J. Manzanilla. MHNLS 13823. First state record, ca. 200 km NE from Guanare, Portuguesa (Markezich 2002). This specimen, along with the next species, represent the first Scolecophidan records from Cojedes (Roze 1966).

Leptotyphlops macrolepis (Cieguita). Municipio San Carlos: San Carlos, 120–140 m elev. 11 November 1989. Mariano Blanco. Verified by J. Manzanilla. MHNLS 13831. First state record, ca. 180 km NE from Mesa de Cavacas, Portuguesa (Markezich 2002).

Acknowledgments.—We are indebted to J. Celsa Señaris (Museo de Historia Natural La Salle, Caracas) and Allan Markezich (Black Hawk College, Illinois) for some comments on the manuscript and providing additional information to us. We thank Luis Yánez (Instituto de Geografía y Desarrollo Regional, Universidad Central de Venezuela, Caracas) for his help with Cojedes geography. Finally, we thank Francisco Bisbal and Ramón Rivero (EBRG) for allowing us to review the collection under their care and for the shared information.

New Records for Amphibians from Counties in South-Central Tennessee

JON M. DAVENPORT
JOSHUA R. ENNEN
and
A. FLOYD SCOTT
Department of Biology and Center for Field Biology
Austin Peay State University, Clarksville, Tennessee 37044, USA
e-mail (AFS): scotta@apsu.edu

Continuing field work in areas of the southern Highland Rim and Cumberland Plateau of central Tennessee has yielded several new county records for species of salamanders and frogs. Most of these records, presented below, are from the contiguous counties of Lincoln, Franklin and Marion, while a few are from Lawrence and Lewis counties.

Records were considered new if the species in question was not reported from one of the above-listed counties by Redmond and Scott (1996) or in literature on Tennessee herpetology published since that date.

All collections were made by one or more of the authors (under authority of Tennessee Wildlife Resources Scientific Collecting Permit No. 1662) and documented with voucher specimens deposited in Austin Peay State University's Museum of Zoology (APSU). Species and subspecies identifications were verified by William H. Redmond. Nomenclature follows that proposed by Crother (2000).

CAUDATA

Ambystoma maculatum. (Spotted Salamander). LAWRENCE CO.: Laurel Hill Wildlife Management Area, wetland between dirt road and Natchez Trace Parkway at mile marker 373 (35°21'32"N, 87°33'05"W). 19 March 2004. APSU 17621. Adult female in vernal pool in deciduous forest. LEWIS CO.: Lewis State Forest, wetland just south of unnamed road ca. 0.2 km E of intersection with Fire Tower Road (35°30'14"N, 87°36'09"W). 19 March 2004. APSU 17624. Adult male under rotting log near woodland pool. MARION CO.: Prentice Cooper State Forest, pond adjacent to picnic area at intersection of Snooper's Rock Road and Tower Road (Suck Creek Mountain Road in Tennessee Atlas and Gazetteer) (35°06'04"N, 85°25'44"W). 6 March 2004. APSU 17639. One adult male from man-made pond in mixed pine-oak woodland.

Ambystoma opacum. (Marbled Salamander). LAWRENCE CO.: Laurel Hill Wildlife Management Area, wet woods between Laurel Hill Lake Road and Natchez Trace Parkway at mile marker 373 (35°21'32"N, 87°33'05"W). 19 March 2004. APSU 17622. Three larvae from vernal pool in deciduous forest. LEWIS CO: Lewis State Forest, wetland just south of unnamed road ca. 0.2 km E of intersection with Fire Tower Road (35°30'14"N,87°36'09"W). 19 March 2004. APSU 17623. Three larvae from vernal pool in deciduous forest. MARION CO: Prentice Cooper State Forest, pond just W of Tower Road (Suck Creek Mountain Road in Tennessee Atlas and Gazetteer) at junction with Snooper's Rock Road near picnic area (35°06'08"N, 85°25'48"W). 6 March 2004. APSU 17644. Five larvae from pond in deciduous forest.

Ambystoma talpoideum. (Mole Salamander). MARION CO.: 1) Prentice Cooper State Forest, pond adjacent to picnic area at intersection of Snooper's Rock Road and Tower Road (Suck Creek Mountain Road in Tennessee Atlas and Gazetteer) (35°06'04"N, 85°25'44"W). 6 March 2004. APSU 17638. One adult female from man-made pond in deciduous forest; 2) Prentice Cooper State Forest, pond along east side of Tower Road (Suck Creek Mountain Road in Tennessee Atlas and Gazetteer) ca. 1.5 km S of state forest boundary (35°09'16"N, 85°24'59"W). 5 March 2004. APSU 17646. Two larvae from small pond in woods opening.

Gyrinophilus porphyriticus porphyriticus. (Northern Spring Salamander). MARION CO.: Prentice Cooper State Forest, spring along south side of Tower Road (Suck Creek Mountain Road in Tennessee Atlas and Gazetteer) ca. 11.25 km S of state forest boundary (36°06'14"N, 87°25'51"W). 5 March 2004. APSU 17633. Older larva from near mouth of spring at edge of deciduous forest.

Pseudotriton ruber ruber. (Northern Red Salamander). LINCOLN CO.: along north side of McFerrin Lane, 0.5 km W of McDeal Road, 1.5 air km NNW of Camargo (35°05'44"N, 86°38'28"W). 5 March 2004. APSU 17633. One adult in moist rotting log near mouth of spring in deciduous forest.

ANURA

Acris crepitans crepitans. (Northern Cricket Frog). MARION CO.: Prentice Cooper State Forest, along west side of Tower Road (Suck Creek Mountain Road in Tennessee Atlas and Gazetteer) at junction with Davis Pond Road (35°05'23"N, 85°25'57"W). 8 May 2004. APSU 17641. Adult at small pond in deciduous forest.

Bufo americanus americanus (Eastern American Toad). Lincoln Co.: along south side of McFerrin Lane, 0.1 km west of McDeal Road, 1.4 air km NNW Camargo (35°05'42"N, 86°38'20"W). 19 March 2004. APSU 17617. Adult male at cattle pond in open field.

Hyla cinerea (Green Treefrog). Marion Co.: floodplain of Tennessee River at river mile 118.5 opposite town of South Pittsburg along north side of TN Hwy 156 (35°00'54"N, 85°41'19"W). 11 June 2004. APSU 17645. Adult male in floodplain marsh, several others calling in vicinity. In addition to representing a new Marion County record, this discovery extends the known range of the species some 80 km up the Tennessee River drainage from the closest known downstream site in Marshall County, Alabama (Mount 1975).

Pseudacris crucifer crucifer (Northern Spring Peeper). Marion Co.: pond along east side of Tower Road (Suck Creek Mountain Road in Tennessee Atlas and Gazetteer) ca. 1.5 km south of state forest boundary (35°09'16"N, 85°24'59"W). 5 March 2004. APSU 17631. Adult male from small pond in woods opening.

Pseudacris feriarum (Upland Chorus Frog). Marion Co.: Prentice Cooper State Forest, along west side of Tower Road (Suck Creek Mountain Road in Tennessee Atlas and Gazetteer) across from Lusk Cemetery, ca. 1.0 km south of lookout tower (35°07'29"N, 85°25'54"W). 5 March 2004. APSU 17629. Adult male in roadside ditch.

Rana catesbeiana (American Bullfrog). Marion Co.: Richard City, Chance Road 0.5 km from junction with Irondale Road (35°00'07"N, 85°44'11"W). 6 March 2004. APSU 17630. One juvenile on road in suburban area.

Rana clamitans melanota (Northern Green Frog). Lewis Co.: Lewis State Forest, tributary to Jacks Branch just east of Fire Tower Road, 0.5 km S of junction with TN Hwy 48 (35°30'40"N, 85°35'51"W). 19 March 2004. APSU 17626. One juvenile in pool of nearly dry creek in deciduous forest.

Rana sphenocephala utricularius (Southern Leopard Frog). Lewis Co.: Lewis State Forest, Fire Tower Road 0.5 km S of junction with TN Hwy 48 (35°30'40"N, 85°35'51"W). 19 March 2004. APSU 17626. One juvenile in roadside ditch bordered by deciduous forest. Marion Co.: floodplain of Tennessee River at river mile 118.5 opposite town of South Pittsburg along north side of TN Hwy 156 (35°00'54"N, 85°41'19"W). 11 June 2004. APSU 17647. Juvenile in floodplain marsh.

Acknowledgments.—Richard, Deborah, and Matthew McFerrin helped in the field and provided housing at Serendipity Farms. Matthew Chance and Darren Moffett assisted with fieldwork in Marion County. Rob Klippel saved specimens and helped locate field sites at Prentice Cooper State Forest. Transportation was provided by Austin Peay State University's Center for Field Biology.

Ballinger et al. (2000) recently reviewed and summarized specimen-based distribution records for amphibians and reptiles in South Dakota, and concluded that knowledge of the regional herpetofauna is incomplete and many county records remain to be documented. We herein report additional county records collected during 2003 and 2004. We consulted regional accounts (Chiszar et al. 1994; Dunlap 1967; Fischer et al. 1999; Fishbeck and Underhill 1959; Over 1923) and the range maps of Ballinger et al. (2000) to determine county records. Unless stated otherwise our identifications were verified by Michael G. Hopewell. Voucher specimens were deposited in the Campbell Museum (CUSC), Clemson University, Clemson, South Carolina, USA.

ANURA

Pseudacris triseriata (Western Chorus Frog). Marshal Co.: 4 km N of Veblen (45°53'16"N, 97°17'27"W). 21 August 2004. Laurs B. J. Williams. CUSC 2250. Adult captured in wetland during intense chorus following evening thunderstorm. This record fills a gap in the distribution of *P. triseriata* in northeastern South Dakota; previously reported in the surrounding counties of Roberts, Clay, and Brown (Ballinger et al. 2000).

Rana catesbeiana (American Bullfrog). Jackson Co.: Craven Creek at Highway 44, 1 km S of Wanblee (43°33'32"N, 101°39'39"W), Pine Ridge Indian Reservation. 16 June 2004. Steven G. Platt and Zannita Fast Horse. CUSC 2253. Adult frogs and tadpoles abundant in man-made impoundment along Craven Creek and also in beaver ponds at Long Creek, 5 km E of Wanblee (43°34'40"N, 101°36'41"W). Our record extends distribution northwards ca. 46 km from populations reported in Bennett and Shannon counties

(Ballinger et al. 2000; Fischer et al. 1999).

TESTUDINES

Chelydra serpentina (Snapping Turtle). FALL RIVER CO.: Highway 18, 4.8 km S of Hot Springs. 3 June 2003. Steven G. Platt. CUSC 2264. Juvenile turtle crossing road along Fall River. Although locally common in suitable habitat (e.g., Hammer 1969), our record constitutes only the fifth specimen of *C. serpentina* from counties west of the Missouri River in South Dakota. A DOR adult found on Highway 18 Bridge at the Cheyenne River, 1 km S of Maverick Junction was heavily damaged and not collected.

Chrysemys picta bellii (Western Painted Turtle). FALL RIVER CO.: Limestone Butte Lake (43°09'36"N; 103°09'47"W), 7.2 km SE of Olerichs, Buffalo Gap National Grassland. 26 May 2004. Steven G. Platt and Zannita Fast Horse. CUSC 2267. Our collection consisted of eight of 86 dead turtles found in drying lakebed. Mortality probably resulted when low water levels during the winter of 2003–04 exposed overwintering turtles to desiccation and lethal temperatures. Previously reported in adjacent Shannon and Custer counties (Ballinger et al. 2000; Fishbeck and Underhill 1959).

LACERTILIA

Eumeces multivirgatus (Many-lined Skink). SHANNON CO.: approximately 2 km E of Wakpamani (43°02'13.9"N; 102°06'31.4"W), Pine Ridge Indian Reservation. 15 June 2004. Steven G. Platt. CUSC 2236. Our record constitutes the third specimen from South Dakota. Previously reported from sandhills in Tripp County and adjacent Bennett County (Ballinger et al. 2000; Malaret 1977). Our specimen was found beneath a clump of dried cattle (*Bos taurus*) dung in lightly grazed sandhill habitat. Others likewise report finding *E. multivirgatus* under dried cattle dung (Hammerson 1999; Taylor 1935).

Holbrookia maculata (Common Lesser Earless Lizard). SHANNON Co: 3 km E of Wakpamani (43°02'15.4"N; 102°06'23.4"W), Pine Ridge Indian Reservation. 15 June 2004. Steven G. Platt. CUSC 2265. Found in sandhills among sparse grass. *Holbrookia maculata* also reported from sandhills in adjacent Bennett County (Ballinger et al. 2000; Fishbeck and Underhill 1959; Maralet 1977).

Sceloporus undulatus (Eastern Fence Lizard). SHANNON Co: Bluffs along BIA Highway 27, 2.6 km S of county line (43°39.954'N; 102°31.534'W), Pine Ridge Indian Reservation. 16 June 2003. Steven G. Platt, Zannita Fast Horse, and Laurs B. J. Williams. Verified by Richard R. Montanucci. CUSC 2161. Found among *Juniperus* sp. on steep slope above eroded White River badlands. Previously reported from sandhills in extreme southern Shannon County at the Nebraska State Line (Ballinger et al. 2000). Our record extends the known distribution ca. 77 km northwards and represents the northernmost record in South Dakota. An additional specimen was collected from sandhills, 2.5 km E of Wakpamani (43°01'56.3"N; 102°07'08.8"W), Pine Ridge Indian Reservation. 11 June 2004. Steven G. Platt and Zannita Fast Horse. *Sceloporus undulatus* is locally abundant at this site with *Holbrookia maculata*.

SERPENTES

Lampropeltis triangulum (Milksnake). SHANNON CO.: 38 km E of Buffalo Gap on BIA Highway 2 (43°28'39"N; 102°55'06"W), Pine Ridge Indian Reservation. 23 June 2003. Steven G. Platt, Zannita Fast Horse, and Laurs B. J. Williams. CUSC 2160. DOR adult male found in extensive grassland. FALL RIVER CO.: 8 km W Edgemont along Highway 18, 1.5 km N of Highway, Buffalo Gap National Grassland. 22 June 2004. Steven G. Platt. CUSC 2266. Two additional snakes observed, but not collected. All snakes were found in rodent tunnels beneath rocks on the rim of steep-sided, but shallow canyons in arid grassland with a significant component of sagebrush (*Artemisia tridentata*). These records fill the distribution gap in extreme southwestern South Dakota; previously reported from Bennett County to the east, and Custer and Pennington counties to the north (Ballinger et al. 2000; Fishbeck and Underhill 1959).

Storeria occipitomaculata (Northern Red-bellied Snake). ROBERTS CO.: 32.1 km NE of Sisseton on County Road 1E at Interstate 29 overpass (45°56'09"N; 96°50'40"W). 27 September 2004. Laurs B. J. Williams. CUSC 2268. Fifth record from eastern South Dakota; also reported in the eastern counties of Lincoln, Minnehaha, and Deuel, although specimens from the latter county lack specific locality data (Ballinger et al. 2000).

Acknowledgments.—Support for this project was provided by Oglala Lakota College and the Natural Heritage Program of the South Dakota Department of Game, Fish, and Parks. We thank Travis Crabtree, Warren Cross, Camille Green, Mike Fredenberg, Valerie Janis, Sylvio Mannel, and Kalyar Platt for field assistance, and Mike Hopewell and Richard Montanucci for verifying the identifications of our specimens. Kent Jensen, Sylvio Mannel, and Jim Taulman suggested promising collecting locales, and Hobart Smith, John Iverson, and Joseph T. Collins provided references. Scientific collecting permit (License No. 19) was issued to Steven G. Platt by Doug Backland, South Dakota Department of Game, Fish, and Parks.

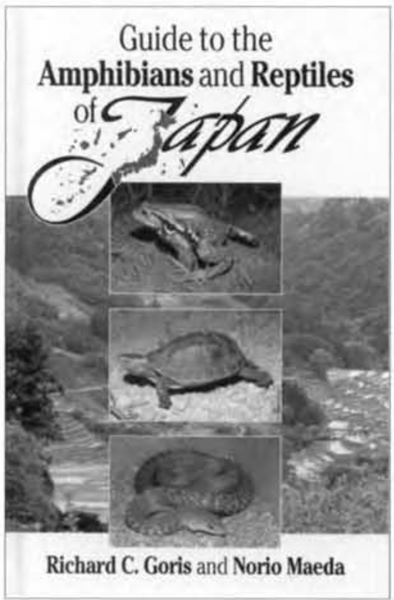
Senbaru 1, Nishihara, Okinawa 903-0213, Japan
e-mail: ota@sci.u-ryukyu.ac.jp



Since its initial insularization in the early Miocene, Japan has experienced a series of land bridge connections to the adjacent Eurasian land mass and been subjected to extensive insularization through complicated tectonic movements (e.g., Chinzei and Machida 2001; Kizaki and Oshiro 1980). Such paleogeographical dynamics, along with its high geomorphological and climatic diversity, have contributed greatly to the taxonomic diversity and endemicity of the herpetofauna of this island country (Hikida 2002; Matsui 1996; Ota 1998).

Comprehensive syntheses of the Japanese herpetofauna in the form of monographs or encyclopedic guides have been attempted by several authors (e.g., Nakamura and Uéno 1963; Sengoku 1979; Sengoku et al. 1996; Stejneger 1907). However, most such works were published in Japanese, and thus had a limited utility to non-Japanese researchers interested in the Japanese herpetofauna. Recent rapid progress in the study of herpetological diversity in Japan (e.g., see reviews by Matsui [2000] and Ota [2000a]) has necessitated up-dating of even the latest carefully prepared works (e.g., Sengoku et al. 1996). The *Guide to the Amphibians and Reptiles of Japan* (henceforth referred to as GARJ), as the latest book to treat the Japanese herpetofauna comprehensively, should be expected to meet these requirements.

Richard C. Goris, the senior author of this book, is a long-time resident of Japan, and is one of the founding members and past President of the Herpetological Society of Japan. While focusing on the anatomy and neurophysiology of the pit organ of snakes, Goris (1966) published *The Reptiles of Japan*, a landmark book introducing in Japanese the reptiles of the main islands and adjacent islets. Norio Maeda, the junior author, is a nature photographer. In the herpetological world, he is famous as the senior author of the *Frogs of Japan*, a bilingual encyclopedic guide (Maeda and Matsui 1989, 1999).

Following the table of contents, the main text of GARJ begins with four pages of general introduction entitled "The Herpetological Environment in Japan." In this section, the authors highlight, with a beautiful photograph of its typical spring landscape, the terrace paddy system in the main islands of Japan called "satoyama" or "yato." They argue that the natural history of Japanese amphibians and reptiles is centered on such habitats. Then, the authors attempt a brief chronological review of major events threatening amphibians and reptiles of "satoyama" since the Pacific War, such as the use of insecticides in paddy fields and intensive collecting of particular species with high commercial value. In this section, the authors also provide a map of the whole Japanese territory (exclusive of a few islands northeast of Hokkaido) divided into four panels—to different scales—and number many of the islands that they define as "herpetologically important." A key below the map names each numbered island or island group.

"Satoyama" is certainly one of the most characteristic habitat types for amphibians and reptiles on the main islands of Japan. However, such an environment is almost completely lacking in the Ryukyu Archipelago, to which, according to the latest Red List of Japan, eight of 14 endangered amphibians and 17 of 18 endangered reptiles are confined (Matsui et al. 2000). To most of those endangered taxa of the Ryukyus, loss of their primary habitat, the humid broadleaf forest, seems to be the most essential threat at present (Ota 2000a).

From the fifth page of the text, accounts, each occupying 1.5–3 pages, are given for 20 species of Urodela, 37 species and five subspecies of Anura, ten species of Testudines, 31 species and one subspecies of Lacertilia, and 38 species and five subspecies of Serpentes. These include not only the native taxa, but also most of the exotic taxa that have already established feral populations in Japan. Nevertheless, a few other established exotics, such as *Chelydra serpentina* and *Trimeresurus mucrosquamatus* (Japan Ecological Society 2002), are not included and even one long-recognized native species of salamander, *Hynobius dunni*, is missing from GARJ.

Each account begins with the scientific name (including authorship), followed by the Japanese and English names, and the subsections "Identification," "Confusing Species," "Distribution," "Reproduction," "Habits," and "Notes." A map, in which the distribution of each taxon is denoted in red, is also provided. Accounts for each anuran species or subspecies include another subsection, "Voice," in which the male acoustic characteristics are briefly described. Likewise, another subsection, "VENOMOUS," is added to the account for each venomous snake. Color photographs are also given in accounts for all species and subspecies except *Emoia atrocostata atrocostata*, *Perochirus ateles*, *Achalinus formosanus chigirai*, *Amphiesma vibakari danjoense*, *Calamaria pfefferi*, *Emydocephalus ijimae*, and *Pelamis platura*.

GARJ is attractive in appearance and gives the impression of being highly useful, particularly to non-Japanese herpetologists interested in the Japanese fauna. Indeed, it offers various interesting and useful pieces of information, including some that can only be provided by a native English speaker with long residence and involvement in herpetological activity in Japan, like Dr. Goris.

Immediately after starting to read its contents in detail, however, I could not help feeling embarrassed because of the high number of obvious errors, inappropriate wordings, and misleading expressions occurring throughout the text.

First of all, several scientific names include obvious errors. For example, the generic name of the tree lizards, *Japalura*, is consistently spelled as *Japarula*. The ending of the specific epithet of the Iwasaki's coral snake should be "*-i*" (i.e., *macclellandi*), but is "*-ii*" in GARJ. Also, the specific epithet of the Iijima's turtle-headed sea snake is correctly spelled *ijimae*, not *iijimae*. The authorship for the scientific name *Cistoclemmys flavomarginata evelynae*, should be Ernst & Lovich, 1990, not (Gray, 1863). Likewise, the authorship of *Hydrophis ornatus maresinensis* is Mittleman, 1947, not (Gray, 1842). The authorships of amphibians and reptiles described in Siebold's (1838) *Fauna Japonica* had once been attributed to Schlegel, 1838 (e.g., see Nakamura and Uéno 1963), but Hoogmoed (1978) clarified that Temminck should be the senior author of those names (also see Zhao and Adler 1993). In GARJ, anuran species described in *Fauna Japonica* (*Bufo japonicus japonicus*, *Rana rugosa*, and *Buergeria buergeri*) are correctly attributed to Temminck & Schlegel, 1838, but curiously enough, Schlegel alone is still credited with authorship of the other species first described in that work (i.e., *Hynobius naevius*, *H. nebulosus*, and *Takydromus tachydromoides*).

Iwasaki's coral snake *Sinomicrurus macclellandi iwasakii* was first described as *Callophis iwasakii*. So, in the current combination, the author should appear in parentheses—(Maki, 1935). The same is true of the authorship of the mourning gecko *Lepidodactylus lugubris*, which was originally described under the generic name *Platydactylus*. In contrast, the authorship of the Otton frog, *Rana subaspera*, should not be in parentheses because Barbour (1908) assigned this species to *Rana* in its original description. This also applies to the author citations for *Eumeces elegans*, *E. japonicus*, *Trimeresurus okinavensis*, and *T. tokarensis*. The specific epithet of the pelagic sea snake should be "*platura*," not "*platurus*," as was recently clarified by Lanza and Boscherini (2000). The date of publication of Hallowell's report is 1861, not 1860, despite the fact that the latter date is printed on its front page (see Zhao and Adler 1993). In GARJ, this is correctly expressed in the citations for frogs (*Rana nigromaculata*, *Buergeria japonica*, and *Rhacophorus viridis*), but not for the newt (*Cynops ensicauda*) or the reptiles (*Ateuchosaurus pellopleurus*, *Cryptoblepharus boutonii nigropunctatus*, *Eumeces latiscutatus*, *E. marginatus*, *Cyclophiops semicarinatus*, and *Trimeresurus flavoviridis*), for which publication dates remain listed as 1860. Incorrect publication dates are also given for *Eretmochelys imbricata* Linnaeus (1776, actually 1766) and *Gehyra mutilata* (Wiegmann)(1835, actually 1834; see Zhao and Adler 1993).

For some scientific names, format of presentation is not consistent with that for the others. The authorship for *Anolis carolinensis*, for example, is shown simply as "(Voigt)" without year of publication (1832). Authorships are not given at all for *Calamaria pavimentata miyarai* and *Elaphe carinata yonaguniensis* (both Takara, 1962). In the scientific names of the species described by Albert Günther, the author's name is spelled as "Günther" for *Hyla japonica* and *Rana dybowskii*, "Gunther" for *Rhacophorus schlegelii* and *Sinomicrurus japonicus japonicus*, and "Guenther" for *Elaphe carinata carinata*. Such an inconsistency, though not completely erroneous, could be misleading to readers.

Taxonomic arrangements and relevant statements are questionable for several taxa. For example, the Ryukyu ground gecko, *Goniurosaurus kuroiwae*, is placed in the family Gekkonidae, despite morphological and phylogenetic distinctness of this and related species, which justifies their separation from the other geckos as a distinct family, the Eublepharidae (e.g., Bauer 2002; Kluge 1987; Underwood 1954). The generic name *Apeltonotus* is used for the Sakishima grass lizard (as *Apeltonotus dorsalis*), although recent phylogenetic studies have invariably indicated its status as a junior synonym of *Takydromus* (Arnold 1997; Lin et al. 2002; Ota et al. 2002). Likewise, *Cistoclemmys* is still used as the generic name for the yellow-margined box turtle, despite recently published convincing evidence for its synonymy with *Cuora* (Honda et al. 2002). In an account for *Chelonia mydas*, the authors note that the Japanese populations have been assigned to the subspecies *C. m. agassizii*. This is not the case at all. The *C. mydas* populations breeding in the Japanese territory, while occasionally referred to as *C. m. japonica* (e.g., Nakamura and Uéno 1963), have never been assigned to this primarily southern Pacific subspecies. I suspect that the authors have misinterpreted a recent report on the discovery of a few *C. m. agassizii* from the Japanese sea (Kamezaki et al. 1998; Ota 2001).

The name *Rana limnocharis* is applied not only to the marsh frog populations of the central Ryukyus and the main islands, but also to the southern Ryukyu populations without any annotation. This is confusing because in another recent publication (Maeda and Matsui 1999), Maeda recognized the latter populations as distinct at the species level. Likewise, the authors synonymize a recently described subspecies of the coral snake, *Sinomicrurus japonicus takarai* Ota, Ito & Lin, 1999, with *S. j. boettgeri* (Fritze, 1894), but without clarifying the reason for doing so.

The greatest taxonomic confusion is seen in the arrangement of the Ryukyu populations of the genus *Amphiesma*. In GARJ, *A. ishigakiense* (Malnate & Munsterman, 1960) is retained as a subspecies of *A. pryeri* (Boulenger, 1887) as *A. pryeri ishigakiensis* (the ending of this subspecific epithet is also inappropriate: see Toriba 1994). Moreover, both "subspecies" are shown in their distribution maps to occur sympatrically in the Miyako and Yaeyama Groups of the southern Ryukyus. Actually, a recent study demonstrated that *ishigakiense* is distinct from *pryeri* sensu stricto not only in coloration and reproductive mode as mentioned in GARJ, but also in scalation, karyotype, and hemipenial morphology. The study also clarified that distribution of the latter is confined to the central Ryukyus (Ota and Iwanaga 1997). Furthermore, recent morphological and chromosomal analyses revealed that the Miyako Group populations of *Amphiesma* deserve recognition as another distinct species under the resurrected name *A. concelarum* Malnate, 1963 (Ota and Iwanaga 1997; Ota and Takahashi 1997).

The worst aspect of GARJ lies in the presentation of geographic distributions. As is mentioned above, the authors presented an introductory map of Japan with a key to names of "herpetologically important" islands. First of all, adequacy in selection of islands for the key is questionable, because it fails to choose several islands with which prominent herpetological events or properties are associated, such as Minamitorishima Island (an islet from which

TABLE 1. Distributional errors at the island level in the maps for terrestrial taxa in GARJ.

Species/Subspecies	Erroneous island records	Islands erroneously omitted	Sources
Hynobius okiensis	An island drawn in the north of Noto Peninsula (see text)	Oki (or Okinoshima)	Sato (1943), Sengoku et al. (1996)
Hynobius tsuensis	Oki (or Okinoshima)	Tsushima	Sato (1943), Sengoku et al. (1996)
Cynops ensicauda	Kikaijima	Akajima, Zamamijima	Ota (1986), Hayashi and Matsui (1988)

TABLE 1. Continued.

Dinodon orientale	Iwojima of the Iwojima Group	Iwojima of the Osumi Group	Nagai (1938)
Dinodon r. rufozonatum		Uotsurijima	Ota et al. (1993)
Elaphe carinata yonaguniensis	Haterumajima	Yonagunijima	Takara (1962), Ota (1981)
Elaphe climacophora		Yakushima, Tanegashima Kuchierabujima[2)]	Nagai (1938), Morita and Ogata (1997)
Elaphe quadrivirgata		The remaining islands of the Osumi Group	Nagai (1938), Morita (1996)
Lycodon ruhstrati multifasciatus		Irabujima	Takahashi (1996)
Trimeresurus elegans	Haterumajima	Taketomijima, Kuroshima, Kohamajima, Okinawajima[1)]	Takara (1962), Ota (1999)
Trimeresurus flavoviridis	Akajima, Zamamijima	Iheyajima, Tokunoshima	Takara (1962)
Trimeresurus okinavensis		Izenajima, Tokunoshima	Takara (1962)
Trimeresurus tokarensis	Unnumbered island in the immediate south of Takarajima	Kodakarajima	Takara (1962)

1) Demonstrably or supposedly of artificial origins (Ota, 1999; Lever, 2003).
2) A small island of the Osumi Group, immediately east of Yakushima Island. Drawn in the distribution maps in GARJ, but not named.
3) Maeda and Matsui (1999) regarded populations from these and other adjacent islands as distinct from *R. limnocharis* at the species level. See text.
4) Information has recently been obtained that suggests the occurrence of *P. sinensis* on Haterumajima Island. However, this needs verification (Ota et al., 2004).
5) The Yonagunijima population of *Japalura polygonata* is now regarded as a distinct subspecies, *J. p. donan* Ota, 2003. See text.
6) The name *Eumeces latiscutatus* (Hallowell, 1861) was long applied to all main island *Eumeces* populations. Motokawa and Hikida (2003) clarified that this is actually a senior synonym of *E. okadae* Stejneger, 1907 (see pp.165-167 of GARJ), and that *E. japonicus* Peters, 1864 should be applied to all main island populations of the genus except for those in the Izu Peninsula.
7) An established population of artificial origin is known from Wakayama Prefecture, southwestern Honshu (Okada, 1998).
8) An established population is known from Oita Prefecture, eastern Kyushu (Kawata, 1982; Okada and Toda, 1999).
9) Referred to as *Amphiesma pryeri pryeri* in GARJ. See text.
10) Referred to as *Amphiesma pryeri ishigakiensis* in GARJ. See text.

Perochirus ateles was first recorded by Burt and Burt [1932] and still remains as one of the only two known localities of the species within the Japanese territory), Kuchinoshima Island (where the northernmost populations of *Buergeria japonica* and *Eumeces marginatus*, and the southernmost, introduced population of *Elaphe quadrivirgata* occur; Hikida et al. 1992), Akusekijima Island (where a distinctly isolated population of *Mauremys mutica* occurs [Yasukawa et al. 1996], and an enigmatic, unidentified *Eumeces* population occurred until being extirpated by introduced weasels a few decades ago: Hikida et al. 1992), Tonakijima Island (type locality of *Goniurosaurus kuroiwae orientalis*), and Nakanokamishima (or Nakanouganjima) Island (where *Dinodon rufozonatum walli* exhibits marked gigantism and peculiar carrion eating habits; Kohno and Ota 1991). Why the authors chose other small islets with apparently much less herpetological importance, such as Taketomijima Island of the southern Ryukyus, is unclear.

Secondly, terminology in the introductory map, particularly in the part of the Ryukyu Archipelago (sensu Ota [1998], i.e., defined as the whole fringing archipelago located between Kyushu, Japan and Taiwan), is not only impractical but also highly confusing. For example, the authors, while dividing the northeastern half of the archipelago (belonging to Kagoshima Prefecture) into three island groups (Tanegashima Group [more conventionally Osumi Group], Tokara Group, and Amami Group), combine all islands in the southwestern half (belonging to Okinawa Prefecture) as the "Okinawa Group." Such a grouping, while possibly bearing some political significance, makes it difficult to refer to some of the biogeographically most distinct units precisely. For example, although many amphibian and reptile species are shared between Okinawajima plus adjacent islets (i.e., the Okinawa Group sensu Ota [1998]) and the Amami Group, far fewer are common between the former and the southern Ryukyus (i.e., the Miyako Group and the Yaeyama Group sensu Ota [1998])(e.g., see Ota 2000b). As a result, the authors use some additional unconventional terms, such as the "Okinawa Archipelago," "Miyako Archipelago," and "Yaeyama Archipelago" in the text. Because these terms are not defined in GARJ or in any other literature, their use could be confusing to non-Japanese readers in particular.

The part of the introductory map showing the Tokara Group largely accurately depicts shapes, relative sizes, and relative locations for more than half of its component islands. However, their associations with island names are totally in error. On the map, the third, fourth, fifth, and sixth islands of the main row from the southwest are referred to as Takarajima, Kotakarajima (actually Kodakarajima), Suwanosejima, and Nakanoshima Islands, respectively. However, Suwanosejima Island is actually the second, and Nakanoshima Island the third island depicted on the map (the southernmost and the fourth are Akusekijima and Kuchinoshima Islands, respectively: see above), whereas the fifth and sixth islands do not exist in reality. Takarajima and Kodakarajima are scaled out and are not shown in this or other parts of the map. These errors are particularly regrettable in that they make it difficult for readers to recognize the location of the so-called Watase's Line, the most profound biogeographical subdivision line for the Japanese herpetofauna that lies on the tectonic strait between Kodakarajima and Akusekijima Islands of the Tokara Group

(Hikida et al. 1992; Ota 1998, 2000b).

There are numerous questionable pieces of information and obvious errors in the distribution maps for many taxa. Some of these are more or less related to taxonomic issues. For example, GARJ does not give an account at all for *Hynobius tenuis*, a salamander species described by Nambu (1991). This implies, though not clearly stated anywhere in the book, that the authors follow the view of Matsui et al. (2002), who regarded this nominal species as synonymous with *H. hidamontanus* Matsui, 1987. Nevertheless, in the distribution map for *H. hidamontanus*, the range of *H. tenuis* (located north of the range of *H. hidamontanus* sensu Matsui [1987]) is not shown. Likewise, GARJ does not refer to *Japalura polygonata donan* Ota, 2003, an endemic subspecies of Yonagunijima Island described in the end of 2003. There are two possible reasons for this: 1) the authors negate such distinctiveness of the Yonagunijima population as argued by Ota (2003), or, more likely, 2) the manuscript of GARJ was completed and forwarded to the printer prior to publication of that description. In either case Yonagunijima should have been marked in red on the distribution map of *J. p. ishigakiensis*, to which its tree lizard population had previously been assigned (Ota 1983). In the distribution map for *Scincella boettgeri*, Uotsurijima Island in the Senkaku Group is marked, as are islands of the Miyako and Yaeyama Groups. It is certain that a skink of the genus *Scincella* occurs on Uotsurijima, but its specific status remains undetermined (Ota et al. 1993) so the basis for the authors' allocation to *S. boettgeri* is unclear.

Maps for a few taxa endemic to particular islands exhibit simple and obvious errors. For example, in the map for *H. okiensis*, an island drawn to the north of Noto Peninsula, which actually does not exist, is marked instead of Oki (or Okinoshima) Island, the only known locality for this species (Sato 1943; Sengoku et al. 1996). Errors of the same kind are seen in the maps for *H. tsuensis* and *Elaphe carinata yonaguniensis*. From these and numerous other obvious errors in the distribution maps for terrestrial taxa (see Table 1 for errors at the island level), I cannot help but wonder if the authors examined the primary sources of relevant information by themselves, or whether they seriously checked their maps while proof-reading.

Even for the maps for terrestrial taxa that are not listed in Table 1, I have concern for the accuracy of information. Of the four large forest-dwelling frogs on Okinawajima Island, for example, *Rana narina* is shown to have much broader range on the island, including its middle part, than the remainder, *R. holsti*, *R. ishikawae*, and *R. namiyei*, that are strictly confined to the northern mountain range. Actually, none of the four species occurs in the middle part of the island, and differences among their ranges are subtle, at best, on the map of this scale (Matsui et al. 2000). In the map for *Hemidacyulus bowringii*, the authors marked all islands of the central and southern Ryukyus. Such a presentation will be interpreted by most readers as indicating that this gecko is recorded from all islands in these regions. It is certain that some previous books for general readers, such as Sengoku (1979), referred to the distribution of *H. bowringii* simply as "the Ryukyu Archipelago." However, this does not necessarily mean that the species occurs on *all* islands of the Ryukyus. Actually, to the best of my knowledge, there is, for example, no record of *H. bowringii* from Iheyajima Island. The same is true for the maps for *H. frenatus*, *Lepidodactylus lugubris*, and *Cryptoblephaus boutonii nigropunctatus*, in which all islands of the Ogasawara Group are marked in red, resulting in false accuracy.

It is far more difficult to outline the range of marine species. However, I have to point out several problems in the distribution maps for marine taxa in GARJ that are unnecessarily misleading to readers. For example, coastal waters of Japan, as far northeast as central Honshu on both the Pacific and the Sea of Japan sides, are shaded red in the map for *Caretta caretta*. This suggests that the authors intend to show the range of waters only in the vicinity of nesting beaches of this species, because sighting, by-catch, and stranding records of this sea turtle are also known from as far northeast as northern Honshu (e.g., Biodiversity Center 2001; Nakamura and Uéno 1963). Obviously, however, this is not the case for the map of *Chelonia mydas*, because, although the nesting beaches of this species in Japan are confined to the Ogasawara Group and the Ryukyu Archipelago (e.g., Suganuma 1994), the shaded area in the map also includes waters adjacent to Kyushu, Shikoku, and the Pacific side of western Honshu. If the authors intended to show the range of *C. mydas* including non-nesting records, coastal waters as north as the northernmost tip of Honshu should have been shaded, and this is also true for *E. imbricata* (see published records compiled by Suganuma [1994] and Kamezaki [1994], respectively).

Distribution maps for the sea snakes also suffer in the same way. For example, red-shaded areas in the maps other than that for *Pelamis platura* are invariably confined to waters adjacent to the central and southern Ryukyus. However, the range of *Emydocephalus ijimae* actually includes the shallow water around the Tokara Group (see Ota [1997] for compiled published records). Likewise, for two oviparous species, *Laticauda laticaudata* and *L. semifasciata*, the northernmost egg-laying sites are known on Iwojima Island of the Osumi Group ("Satsunan-Iwojima" in GARJ). In the northern Ryukyus, a few other egg-laying sites are also known for these two species (Nagai 1928; also see Ota [1995] for compiled published data).

In the text of GARJ, there are also a number of questionable statements and inconsistencies of various categories that might be misleading to readers. For example, the authors state that "the Honshu populations of *Mauremys mutica* are thought to stem from introductions from the Chinese mainland," although available information regarding the relevant traffic in the past (e.g., Takashima 1940) and morphological data (Yasukawa et al. 1996) suggest Taiwan to be the most likely origin for these populations. The authors, while noting for some species the artificially introduced origin of certain populations (see above example of *M. mutica*), do not mention this for other species that actually have feral populations within Japan (e.g., all Ryukyu populations of *Pelodiscus sinensis* are of artificial origin: Sato and Ota 1999). For some species, such as *Ramphotyphlops braminus*, *Dinodon rufozonatum rufozonatum*, and *Pelamis platura*, distributions outside the Japanese territory are also mentioned, whereas such information is completely omitted for other species including those that actually have broad extralimital distributions (*Salamandrella keyserlingii*, *Hemidactylus frenatus*, *Laticauda colubrina*, etc.). Such an inconsistency in the extent of documented range among the species will lead to overestimation by the readers of the level of endemism of the Japanese herpetofauna.

In the "Reproduction" subsection for *Ramphotyphlops braminus*, the authors describe its eggs to be 3–4 mm long, but available data indicate that they are actually much longer, varying from 11.2–20 mm (Kamosawa and Ota 1996). They mention that *Cyclophiops herminae* is "probably oviparous, but data are lacking." Actually, observation of a clutch of nine shelled eggs has already been reported for this species (Ota 1996). Obviously, reproductive traits are documented for some species on the basis of data not only from the Japanese populations but also from extralimital populations (e.g., see data given for *Hydrophis cyanocinctus*). For other species, however, data only from domestic populations are considered. It is mentioned, for example, in the account for *Hemidactylus bowringii* that the species is "probably oviparous, but data are lacking," although relevant information is available for its non-Japanese populations (e.g., Ota and Lin 1997). The authors write that *Opisthotropis kikuzatoi* feeds on tadpoles, fish, aquatic insects, and freshwater crustaceans. However, the small crab is the only food item presently known for this endangered, strictly protected species (Nakachi et al. 1993; Ota and Mori 1985). For this snake, the authors also write that one museum specimen collected in October contained eggs in the oviducts. Actually, however, the specimen had been in captivity for several months when it was fixed in October, and it had fairly enlarged ovarian follicles, not oviductal eggs, at fixation (Ota and Mori 1985).

The authors noted that *Tylototriton* (*Echinotriton*) *andersoni* is "now protected by law *in parts* of its range." However, with the recent designation of its Amami populations as a natural monument by the Kagoshima Prefectural Government, the species is now actually protected in its *whole* range. For some species, such as *Rana holsti*, the endangered and protected status are mentioned. For other protected species, including those even at higher red list status and conservation priority (*R. ishikawae*, *Opisthotripis kikuzatoi*, etc.; Matsui et al. 2000), those aspects are not mentioned at all. Such an inconsistency is of particular concern, because it will be misleading to potential collectors of amphibians and reptiles.

In summary, how should I evaluate GARJ? This is the first comprehensive English guide to the Japanese amphibians and reptiles. In this book, more than 95% of the Japanese species are introduced with beautiful photographs. These two facts alone will make GARJ a worthwhile purchase, despite its rather expensive price. However, readers, especially those who want to utilize the book as a source of data for their professional research, should keep in mind that this book is not carefully edited or bibliographically precise, and that it has many errors, misleading inconsistencies, and false accuracies as criticized above.

In Japan, quite a few herpetological data are published every year in periodicals and books written chiefly or exclusively in Japanese. Outside Japan, however, most such data remain unnoticed, or even if noticed, are often excluded from citation in journals whose editors regard such sources of data as the "gray literature." A book like GARJ should have been a good place to gather and synthesize such "hidden" data, but unfortunately the authors did not take advantage of this opportunity. This fact, as well as continuing discoveries on the actual diversity and characteristics of the Japanese herpetofauna (e.g., Matsui et al. 2004; Ota 2003, 2004), makes it greatly desirable to carefully revise this book or, alternatively, to publish more carefully prepared books of this kind in near future.

Acknowledgments.—I thank Kimitake Funakoshi, Sen Takenaka, and Naoki Kamezaki for providing pertinent literature. Manuscript preparation was partially supported by a Grant-in-Aid for the 21st Century COE Project at the University of the Ryukyus from the Japan Ministry of Education, Sports, Culture, and Science (Monbukagaku-sho).

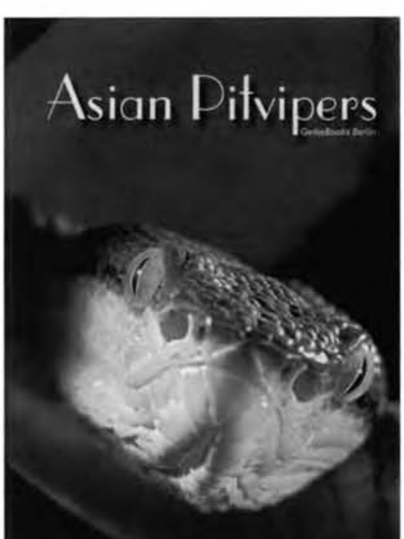
VAN WALLACH
Museum of Comparative Zoology
Harvard University, Cambridge, Massachusetts 02138, USA
e-mail: vwallach@oeb.harvard.edu



This large format hardbound book (21.0 x 29.5 cm) is a breathtakingly beautiful work of art. In fact, the title of this book would more appropriately have been "Photographic Atlas of Asian Pitvipers," which more accurately describes its contents. The quality of the photography is excellent, on par with that of Chanard et al. (1999), Orlov et al. (2002), and Whitaker and Captain (2004), as the majority of photographs

were taken by Gumprecht, Orlov, Grossmann, Tillack, and Captain. The color photos are enhanced by the glossy texture of the paper.

In addition to the 312 pages of photos (1179 figures), there are 42 pages of text (with four pages of scale counts and a 26-page checklist), eight pages of bibliography, a four-page index, and two pages of photographic credits. The summary scale counts given in the table include dorsal scale rows, ventrals, subcaudals, and supralabials with the ventrals and subcaudals listed separately for males and females. Rare states of dorsal scale rows and supralabials are listed parenthetically.

Useful additions to the checklist include the original citation, listing of the type material and type locality, distributional range by country and state, a list of significant references pertaining to the taxon, and systematic comments noting recent taxonomic changes or controversial opinions regarding the status. The paper by Malhotra and Thorpe (2004), which revised Asian pitviper taxonomy with the resurrection of three genera and proposal of four new genera, appeared too late for the authors to follow the latest nomenclature. However, a conversion table is presented on page 11 for reference. The changes include *Ovophis* (with separation of *Garthius*) and *Trimeresurus* (with separation of *Cryptelytrops*, *Himalayophis*, *Parias*, *Peltopelor*, *Popeia*, and *Viridovipera*).

The snakes are presented in alphabetical order by genus and species (the same arrangement as the checklist). The photos vary in size and range from 1–8 per page, the number per page being most commonly 3 (158 pp.), followed by 4 (83 pp.), 5 (29 pp.), 6 (28 pp.), 2 (6 pp.), 8 (5 pp.), 1 (2 pp.), and 7 (1 p.). In addition to 44 habitat shots, the number of photos of each genus is as follows: *Calloselasma* (17), *Deinagkistrodon* (12), "*Gloydius*" (97, with 12 of *Garthius*), *Hypnale* (15), *Ovophis* (87), *Protobothrops* (123), *Triceratolepidophis* (14), "*Trimeresurus*" (686, with 234 of *Cryptelytrops*, 37 of *Himalayophis*, 80 of *Parias*, 12 of *Peltopelor*, 57 of *Popeia*, and 72 of *Viridovipera*), *Tropidolaemus* (71), and *Zhaoermia* (13). These are both aesthetically arranged and conveniently grouped such that all of the photos on a given page are of the same species. Full-body (dorsal, lateral, and ventral) shots of snakes predominate, followed by close-ups of the head (dorsal, lateral, and ventral), tails, hemipenes, egg clutches with hatching neonates, and feeding specimens. When living material is not available, good color photos are provided of preserved and type specimens. Neonates, juveniles, and adults are figured. Some of the photographs (or nearly identical photos) in this book were previously published in other works, including Chan-ard et al. (1999), Orlov et al. (2002), and Whitaker and Captain (2004).

My chief criticisms of the book are the complicated method of numbering plates, lack of identification keys to the genera and/or species, and lack of synonymies for all taxa. Instead of consecutively numbering the photos, the figures are renumbered with Roman numerals on each page, necessitating reference to two values to denote a particular photo (i.e., p. 253 no. II, 253 II, or 253-II). This will make reference to these figures in the literature complicated, lengthy, and possibly misleading.

In a monumental work such as this, which will obviously be the volume on Asian Crotalinae for years to come, it would be expected that a key to at least the included genera and possibly also the species be included. Such keys should not have been difficult to produce considering the authors experience and vast array of excellent photographs.

Synonymies of different names, junior synonyms, and various combinations are vitally important in a work of this magnitude. However, the authors provide only the original combination for each species or subspecies. It is difficult or impossible to assign other names without a good synonymy. Thus, David and Ineich (1999) or McDiarmid et al. (1999) are essential companions to the present atlas even though recent taxonomic changes have been included in the taxonomic listing of the present work. In comparison with the taxonomy of McDiarmid et al. (1999), Gumprecht et al. (2004) includes recognition of the genera *Protobothrops* and *Zhaoermia* and the species *Gloydius brevicaudus*, *Ovophis tonkinensis*, *O. zayuensis*, *Trimeresurus andersoni*, *T. insularis*, *T. malcolmi*, *T. mcgregori*, *T. venustus*, and *T. yunnanensis*; transference of both subspecies *caucasicus* and *stejnegeri* from *Gloydius intermedius* to *G. halys*; synonymizing *Gloydius saxatilis* with *G. intermedius* and *Trimeresurus karanshahi* with *T. tibetanus*; and inclusion of the newly described *Gloydius tsushimaensis*, *Trimeresurus gumprechti*, and *T. vogeli*).

In addition, I noted a two minor typographical errors: *Cryptelytrops andersonii* vs. *andersoni* (p. 11), *Tropidolaemus wagleri* Boie, 1827 vs. *Tropidolaemus wagleri* (Boie, 1827) (p. 41) and a single taxon, *Gloydius blomhoffii dubiatus* Gloyd (1977), was omitted. A few other taxonomic changes and additions are too recent to have been incorporated into the book. The validity of *Cryptelytrops kanburiensis* and *C. venustus* has recently been supported by David et al. (2004). A new species, *Trimeresurus truongsonensis*, has been described from Vietnam by Orlov et al. (2004). It resembles *Cryptelytrops kanburiensis* and *C. venustus* and should probably be referred to that genus. A revision of *T. popeiorum* by Vogel et al. (2004) contains the description of two new species, *T. fucatus* and *T. nebularis*, plus the elevation of the subspecies *T. p. barati* and *T. p. sabahi* to full species status (=*Popeia* of Malhotra and Thorpe, 2004).

This book is not only a terrific bargain for the quality and quantity of the color work but also a must for all herpetologists, toxicologists, biologists, and naturalists. It provides a much needed synopsis of the pitvipers of Asia with excellent photographs to aid in the identification of any species. I highly recommend this book for both the scientist and layman as it is the most comprehensive treatment of Asian pitvipers to date.

In this book the authors attempt to present current information on captive care and natural history of most of the snakes of the United States and Canada. The work is a compilation and updating of two earlier volumes by the authors (Rossi 1992; Rossi and Rossi 1995). The goal of the authors was to present a diversity of information from a wide variety of sources in a format that would be useful to herpetoculturists and professionals wishing to maintain captive North American snakes. For each species they offer both basic natural history information and observations on captive care obtained from amateur and professional herpetologists. They do this by combining personal communications, regional literature from field guides, and scientific paper—primarily from the herpetological journals. Information derived from their own efforts to keep most of the species make up another part of the data presented, particularly for many of the lesser known snakes. Because of the scattered nature of the literature, those keeping snakes often have little information on the natural history of the species and many tend to keep all snakes under the same captive conditions. This book organizes the relevant information in a single source, and in so doing makes a significant contribution to the work of herpetoculturists and others keeping snakes.

Part I of the book is a long, detailed review of the methods for maintaining snakes in captivity. Although most of this information is not new, having it in this volume will be useful for persons with limited experience keeping members of this group, e.g., biologists beginning projects with new species or amateurs beginning in the hobby. It will, however, contribute little to experienced hobbyists, although observations from the authors' own experiences do add some interesting details.

Parts II and III consist of individual species accounts for nonvenomous and venomous snakes, respectively. The accounts include information on natural history and captive conditions and care. A typical account includes a short description, a range map, and a color plate of each species plus a table with a summary of captive requirements (maintenance difficulty index, cage size, appropriate substrate for the cage, and prey types eaten). The information is attractively presented and easy to read, even if it does not add tremendously to our knowledge of most of the species dealt with. We do, however, give the authors a lot of credit for keeping unusual species, such as hooknose snakes, that require spiders and scorpions as food. Indeed, this book might encourage more research on the many species that have typically been rejected as laboratory animals because too little was known about their requirements in captivity. For some such species almost nothing is known about behavior and future captive studies could make real contributions.

There are a few taxonomic problems with this volume, the black-and-white drawings are not very professional, and the scientific literature is not complete. Nonetheless, overall the authors accomplished what they set out to do. They have produced an attractive and readable summary of information as how to best maintain individual species of snakes found in the United States and Canada. The book will be of value to both amateur and professional herpetologists keeping snakes and also anyone else wishing to learn a little more about some of the less well-known North American species.

This wonderfully eccentric volume put me in a nostalgic and envious state of mind. From about the age of nine onward I checked out publications about nature from public and military base libraries wherever our family lived, seeking information on the box turtles, house geckos, and other "creepy crawlies" I'd caught, as well as longing, in some immature way, to understand why they enthralled me. Some of those books also undoubtedly fueled my naive wanderlust. Early on there was *Bring 'Em Back Alive*, by Frank Buck, and *I Married Adventure*, by Osa Johnson—but all that sticks in my mind from the former is a captive tapir that attacked the swashbuckling animal collector, and of the latter my only lasting impressions are of its fake zebra skin binding and Martin Johnson's abrupt death in a plane crash. I also read over and over again the popular works of Raymond L. Ditmars and Clifford H. Pope, each consisting mainly of factual summaries, whereas Carl Kauffeld's legendary *Snakes and Snake Hunting* evoked in me the joys of finding and catching herps. None of those books said much about becoming a professional biologist or how I might earn a living studying frogs and snakes, information that I gleaned instead from correspondence with Charles Bogert, Roger Conant, Henry Fitch, Laurence Klauber, William Milstead, and other luminaries. I still remember their unstintingly generous letters when I answer queries from youthful aspirants, but until now I've had no detailed accounts to recommend of the day-by-day *doing* of contemporary herpetology.

In fact, the editors' stated "primary goal" for *Islands and the Sea* "was to document the constantly evolving history of research" in the Caribbean, as well as to educate, to encourage further herpetological investigations in the region, and to entertain. After a thoughtful introduction by Henderson and Powell, there are 29 essays by 30 authors arranged in sections for the Bahamas, Cuba, Jamaica, Hispaniola, Puerto Rico, and the Lesser Antilles. One could complain about the small size of many of the black and white photos, but if the alternatives were their exclusion or a prohibitively expensive book, the series editor made the right decision. The few other things about which one might grumble, like a surprising number of inappropriately hyphenated words and some political commentaries that seem a bit unbalanced, are trivial in the face of the many strong points of this volume. Overall the editors have succeeded admirably in each of their goals, as well as provided a welcome set of readings for novice herpetologists.

The contributors to *Islands and the Sea* include undergraduates, graduate students, well-seasoned researchers, and a "retired" expert now in his 90s; among them are five women and seven citizens of Caribbean nations. Their prose is often straightforwardly descriptive, but it is rarely plodding and sometimes profound. There are some excellent opening hooks, of which my favorites are by Richard Sajdak ("Feeling less like General Douglas MacArthur than probably anyone in history, I jumped off the deck of the boat into warm knee-deep water"), Rafael Joglar ("I was born on an island where everybody is crazy about frogs"), Karim Hodge ("Six hundred years ago, when the devil was still a boy, Anguilla reclined in complete innocence at the junction of the Caribbean Sea and Atlantic Ocean"), and Ellen Censky ("I woke suddenly with my heart racing and my voice caught in my throat"). The essays mostly recount particularly memorable field trips, the goals of which were faunal inventories or even finding some particular taxon; others concern a doctoral dissertation project (Censky's "Dog Island Days"), long-term population monitoring (John Iverson and his students' "Adventures of the Iguana Patrol"), and the integration of science with education (Allison Alberts' "Conserving the Remarkable Reptiles of Guantanamo Bay").

Islands and the Sea is replete with fascinating natural history anecdotes, of which the one that most surprised me was Sixto Incháustegui's mention of female *Crocodylus acutus* that carry their babies for several kilometers, from nest sites on islets in a saline lagoon to fresh water on "mainland" Hispaniola. Every essay conveys the adventure of fieldwork and expresses a concern for conservation; over and over, the authors speak unabashedly, even poignantly of their love for people, animals, plants, and places. Scattered throughout the volume are thrills and scary times, an occasional personal epiphany, and even a moving tribute to a lost mentor.

Of course the text is specific to islands, and it conveys an authentic feel for the sights and smells of oceans and nearby terrestrial habitats, of the hazards of boat travel and the simple pleasures of rural living. There are also recollections of magical places and the discovery of previously unseen species, those universals of field biology that could just as well have happened high in the Hindu Kush or around some Saharan oasis. Although in some sense all of the essays convey details of historical interest, the editors' primary goal of shedding light on the chronicles of Caribbean herpetology is especially well satisfied in their own essay and in the fine accounts by Orlando Garrido, James Lazell, Michel Breuil, Stanley Rand, and George Gorman. Future analyses are best served by history that doesn't shy from the strengths and weaknesses of its human participants, and thus I particularly appreciated the candid perspectives on the early years of Harvard-based *Anolis* research. And as emphasized by almost every author, these hundreds of islands still offer unanswered questions galore for 21st century scientists.

Islands and the Sea offers an eloquent, honest, and informative look at the lives and work of a diverse bunch of field biologists, one that will appeal to established professionals and neophytes alike. This book helped me remember again why and how I got into science, and I've already given my review copy to a talented teenager. She too wants to be a herpetologist.

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.html>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor.

Advertising

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Dr. Theodora Pinou, SSAR Treasurer, Western Connecticut State University, Department of Biological & Environmental Sciences, 181 White Street, Danbury, Connecticut 06810, USA. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below), regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 760	$320

Herpetological Review

Volume 36, Number 2
June 2005

TABLE 1. Presence of physical characteristics in male and female *Uroplatus henkeli*.

Sex	N	Vertebral stripe	Dorsal striations	Cranial markings
Male	50	19 (38.0%)	50 (100%)	2 (4.0%)
Female	50	0	0	45 (90.0%)

The horizontal black marking on the cranium (Fig. 2) was observed in 90% of the females and 4% of the males (Table 1). Thus our data are strongly suggestive of juvenile sexual dimorphism in *Uroplatus henkeli*.

Acknowledgments.—We thank Keith Benson, Orinna Clark, and Jim Clark for their helpful comments with the text.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 36, Number 1 (March 2005).

CAUDATA

ENSATINA ESCHSCHOLTZII OREGONENSIS* x *PICTA (Oregon x Painted Salamander Intergrade). **BEHAVIOR.** *Ensatina eschscholtzii* is the most widespread and common plethodontid salamander in western North America, with the range extending from southern British Columbia to northern Baja California (Stebbins 1985. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 336 pp.). However, little is known about the climbing behavior of this salamander. In addition, little is known about the climbing behavior of *Batrachoseps attenuatus* or *Taricha granulosa* (Hayes and Hayes 2003. Herpetol. Rev. 34:45–46; Aubry 2000. J. Wildl. Mgmt. 64:1041–1052; Jones and Aubry 1985. Herpetol. Rev. 16:26; Stebbins 1954. Univ. California Publ. Zool. 54:47–124).

An extended period of observation of the climbing behavior of terrestrial salamanders and their use of stumps as habitat was performed from 23 Nov 2001 to 29 Mar 2003. The site is located within the coastal redwood region of Humboldt County, in a semi-rural area of Westhaven, California USA (T8N R1E SW1/4 Sec 31; elev. ca. 100 m) (Sundell and Norman 2003. Herpetol. Rev 33:4). The stumps were Redwood (*Sequoia sempervirens*) that were logged five decades ago. The forest canopy consisted of old-growth Sitka Spruce and second growth Redwood, with few Red Alder (*Alnus rubra*) and Cascara Buckthorn (*Rhamnus purshiana*) in the understory.

On 29 Jan 2001, two subadult female *E. eschscholtzii* intergrades were found on a Redwood stump (stump #1) covered with introduced English Ivy (*Hedera helix*) under a piece of Redwood bark in site 5. The stump was 6 m diam with Evergreen Huckleberry (*Vaccinium ovatum*) and spruce seedlings present on top of the stump ca. 1 m off the ground. The cover object measured 30 x 20 x 4 cm with a temperature of 11.4°C in the covered litter and English Ivy roots. The first female measured 7.3 cm TL and 3.6 cm SVL (measured to the anterior edge of cloaca), the other female measured 7.6 cm TL and 3.9 cm. SVL

On 16 Feb 2002, an *E. eschscholtzii* adult male intergrade (10.4 cm TL, 4.6 cm SVL) and a *B. attenuatus* were found 1.2 m off the ground on another redwood stump (stump #2), under litter, which was 8°C measured at a depth of 9 cm. The stump measured 5.2 m diam and was covered by False Lily-of-the-Valley (*Maianthemum dilatatum*) and two young spruce trees, which measured 4 cm in diameter.

On 2 Mar 2002, an adult male *E. eschscholtzii* intergrade (9.3 cm TL, 4.5 cm SVL) was found under litter on stump #2. This male was marked as LF2 RF2. The litter temperature was 7.3°C, which was measured at a depth of 9 cm. In addition, springtails, centipedes, and arachnids were located in the litter.

On 16 Mar 2002, an adult female, *E. eschscholtzii* (10.5 cm TL, 5.1 cm SVL) was found on another redwood stump (#3), 4.5 m diam. This salamander was wedged between pieces of outer bark, located 1.6 m off the ground.

The first stump was inspected again on 6 April 2002, and produced a female Rough Skinned-Newt (*Taricha granulosa*) (11.7 cm. TL, 4.7 cm SVL). The newt was found under the same piece of bark as the previous Ensatina salamanders found on top of stump #1. Also, present under the cover object with the newt was an adult *B. attenuatus*, which escaped capture.

On 16 Nov 2002, a subadult female *E. eschscholtzii* (7.6 cm TL, 4.1 cm SVL), was found under litter on stump #2, with a litter temperature of 10.8°C. Then again, on 25 Jan 2003, an adult male *E. eschscholtzii* (9.6 cm TL, 5.0 cm SVL), was found on the same stump, with a litter temp of 13.0°C. However, this was a recapture of the adult male (LF2RF2), first captured on 2 Mar 2002, on the same stump #2. Again, three more *B. attenuatus* juveniles were located under litter on top of the same stump. The litter had a temperature of 9.8°C at a depth of 9 cm.

On 15 Mar 2003, a subadult Wandering Salamander (*Aneides vagrans*) (7.4 cm TL, 4.1 cm SVL) was located on a Redwood stump (stump #4) with a subadult *B. attenuatus* (7.2 cm TL, 3.2 cm SVL), under a Redwood cover object 78 cm x 40 cm x 28 cm, which was located 1.5 m. above the forest floor. Stump #4 measured 3.1 m diam. The temperature in the interstitial space was 12.0°C.

Finally, on 29 Mar 2003, three more subadult *B. attenuatus* were located under litter on top of stump #2, which had a litter temperature of 11.7°C covering the coiled salamanders.

These observations emphasize the colonization of tree stumps

by the terrestrial salamanders *E. eschscholtzii* and *B. attenuatus*, and the semi-aquatic salamander, *T. granulosa*, which are not known for their arboreal behavior. In addition, these observations might indicate additional areas that should be searched during salamander surveys to increase the number of individuals observed.

Bradford R. Norman and Thomas A. Kirk assisted with field observations. In addition, I thank the landowners, John and Carol Wiebe, for their support and enthusiasm for this project and permission to conduct observations on their property.

Submitted by **JACOB J. SUNDELL**, 1026 B Westhaven Drive, Trinidad, California 95570, USA.

EURYCEA BISLINEATA (Northern Two-lined Salamander). **LARVAL MICROHABITAT**. Published accounts of the microhabitat of *E. bislineata* larvae include hiding under small stones at the bottom of small pools in streams, under stones at the water's edge, under leaves and on the bottom in slow-moving pools in streams, on the bottom of a glacial lake, and in a small farm pond (Bahret 1996. J. Herpetol. 30:399–401; Brophy and Pauley 2001. Herpetol. Rev. 32:98–99; Dunn 1926. The Salamanders of the Family Plethodontidae. Smith Coll., Northampton, Massachusetts, 446 pp.; Hudson 1955. Herpetologica 11:202–204; Petranka 1998. Salamanders of the United States and Canada, Smithsonian Inst. Press, Washington, DC. 587 pp.). We have observed larvae under rocks in open water, among leaf litter in small pools in mountain streams, and along the stream edge in coarse, wet gravel. Use of living vegetation by these larvae has not been reported previously.

We surveyed a section of the Staunton River 10–500 m upstream from its confluence with the Rapidan River in Shenandoah National Park, Madison County, Virginia, on 20 August 2001 in an ongoing study of streamside salamanders. Until 27 June 1995 the Staunton River was a cool mountain stream with moss-covered rocks and boulders under a full forest canopy. A major rain event that day exceeding 60 cm in a 6-h period caused massive flooding and completely altered the structure of the stream and its surrounding environment (Smith et al. 1996. Water Res. Bull. 32:3099–3113). The stream was scoured several meters deep and the entire canopy, ground vegetation, and original substrate was lost. The open stream corridor was subsequently invaded by early colonizing vegetation such as Woolly Mullen (*Verbascum thapsus*) on the banks above the stream and Spotted Touch-me-not (*Impatiens capensis*) along the water's edge.

We observed an aggregation of ca. 50 *E. bislineata* larvae under and within a thick, filamentous root mass of a Spotted Touch-me-not at the stream edge. Root filaments were ~50 cm long and extended ~20 cm from the overhanging bank into the water in a stream pool. Larvae swam easily in and out of the root mass but were difficult to capture unless they were coaxed into free water. The small interstices among the root filaments appeared to provide adequate cover from syntopic predators such as Brook Trout (*Salvelinus fontinalis*) and salamanders (*Gyrinophilus porphyriticus*, *Desmognathus monticola*). Larval size (TL 21–41 mm, mean 27.2 + 4.5; N = 19) suggested they may have been a mix of one- and two-year old age classes (Petranka, *op cit.* and refs. therein). Ten other larvae captured in the stream that day were 25–59 mm TL. Larval *Eurycea* spp. might aggregate in microhabitats opportunistically that provide concealment. This might help to explain why they are captured in large numbers in leaf litter bags (e.g., Waldron et al. 2003. Applied Herpetol. 1:23–36).

Submitted by **JOSEPH C. MITCHELL**, Department of Biology, University of Richmond, Richmond, Virginia 23173, USA (e-mail: jmitchel@richmond.edu); and **WILLIAM BROWN**, Blue Ridge Biological, 978 Bull Yearling Road, Stanardsville, Virginia 22973, USA.

EURYCEA BISLINEATA (Northern Two-lined Salamander). **LARVAL SIZE.** Maximum larval size in this species varies geographically. Here we report on maximum larval size at the southern edge of the range of this salamander.

On 19 July 2003 we captured seven *E. bislineata* larvae in a small woodland stream on a steep slope within a portion of the Fredericksburg and Spotsylvania National Military Park (NPS) in the City of Fredericksburg, Virginia (30°18"28'N, 77°27"17'W). We assigned these larvae to *E. bislineata* based on the location of the site at the southern edge of its known range (Petranka 1998. Salamanders of the United States and Canada, Smithsonian Inst. Press, Washington, DC. 587 pp.; Mitchell and Reay 1999. Atlas of Amphibians and Reptiles in Virginia. Spec. Publ. No. 1, Virginia Dept. Game and Inland Fisheries, Richmond, Virginia. 122 pp.). The habitat was in mixed hardwoods near a heavily-traveled urban road adjacent to the floodplain of the Rappahannock River. Water temperature was 20ºC. The seven larvae ranged from 51–79 mm TL (29–43 mm SVL). One 74 mm TL individual had reduced gills, whereas the largest one and a 70 mm TL individual had large, filamentous gills. All three of the largest larvae had the dark lateral pattern typical of adult *E. bislineata* in this area (Fig. 1). The occurrence of such large larvae at the southern edge of its range suggests that larval periods of three years may not be limited to cold water environments in the north or that other factors may influence age and size at metamorphosis in this species.

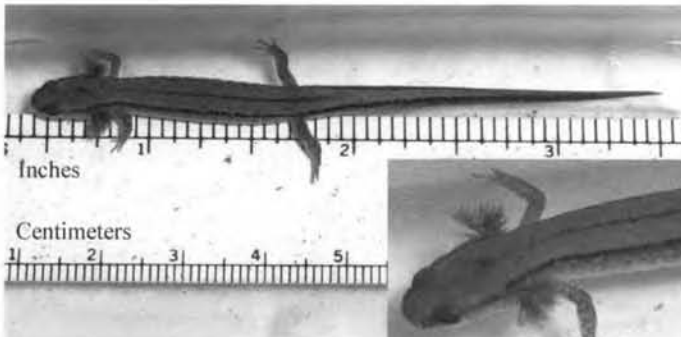

FIG. 1. *Eurycea bislineata* larva (79 mm total length) with large gills from Fredericksburg, Virginia. Photo by W. Brown.

Submitted by **JOSEPH C. MITCHELL**, Department of Biology, University of Richmond, Richmond, Virginia 23173, USA (e-mail: jmitchel@richmond.edu); and **WILLIAM BROWN**, Blue Ridge Biological, 978 Bull Yearling Road, Stanardsville, Virginia 22973, USA.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander) **NESTING ECOLOGY**. Little is known about the nesting ecology of *Hemidactylium scutatum* in Wisconsin (Vogt 1981. Natural History of Amphibians and Reptiles of Wisconsin. Milwaukee Public Museum). During late May and early June 2002, we conducted surveys for nesting *H. scutatum* at three separate ponds at The Ridges Sanctuary and Toft Point State Natural Area (hereafter RS-TP) in Door County, Wisconsin, USA (T30N R28E Secs 3, 4, 9, 10, 15, 16, 17, 21, 22). Dominant woody vegetation surrounding the ponds included White Cedar (*Thuja occidentalis*), Paper Birch (*Betula papyrifera*), Tamarack (*Larix laricina*), Black Spruce (*Picea mariana*), Eastern Hemlock (*Tsuga canadensis*), and Speckled Alder (*Alnus rugosa*). Emergent vegetation within the ponds included Cattail (*Typha latifolia*), sedges (*Carex* sp.), and Marsh Marigold (*Caltha palustris*). All ponds had considerable moss (mostly *Sphagnum* sp.) growth along their perimeters.

The nest survey consisted of searching mosses, moss-covered islets, sedge mats, and fallen logs along the margins or within the ponds. Once a nest was located, we recorded the vertical position of the nest in relation to the water surface, the water depth (cm) below the nest, the snout–vent length (SVL) (mm), and total length (TL) (mm) of all females present, and the number of eggs. We classified nests into four categories based on the nest forms described by Breitenbach (1982. J. Herpetol. 341–346). Nest forms included: 1) solitary, 2) solitary with neighboring nests on the same islet, 3) double (eggs of no more than two females), and 4) multiple (eggs of three or more individuals). Solitary nests were defined as having no more than 40 eggs, all of which were the same stage of development. Double nests were defined as having between 41–79 eggs, whereas multiple nests were defined as having greater than 80 eggs. We considered double and multiple nests to be joint or communal.

Thirty *H. scutatum* nests were located within cavities in moss. No nests were located in sedge mats or decaying logs. Nests were positioned between 7–19 cm (mean 12.87, SD 3.81) above the water surface. Water depth below the nest ranged from 1.5–12 cm (mean 7.76, SD 3.28). Fifteen of the 30 nests had a female attendant at the time of discovery. No more than one female was found in any nest. Female SVL ranged from 33.26–43 mm (mean 36.46, SD 2.47 mm) and TL ranged from 65.66–94.96 mm (mean 84.49, SD 8.06 mm). The total number of eggs per nest ranged from 17–200 (mean 51.30, SD 37.02). Of the 30 nests found, the majority were classified as either solitary (40%) or double (37%). Four nests were solitary with neighboring nests on the same islet, and only three nests were considered multiple. The three multiple nests contained 100, 115, and 200 eggs and all lacked a female guardian. Approximately 46% of nests were considered joint.

Nest searches at RS-TP provided the first site examination of nesting *H. scutatum* in Wisconsin. The relative frequency of joint nesting during Spring 2002 at RS-TP was higher than most published accounts (Gilbert 1941. Copeia 1941:47; Wood 1953. Amer. Nat. 87:77–86; Harris and Gill 1980. Herpetologica 36:141–144.; Breitenbach 1982. J. Herpetol. 16:341–346), however Blanchard (1934. Copeia 1934:137–138) found 61% of nests in a Michigan population to be communal. This research was funded by The Ridges Sanctuary and Cofrin Center of Biodiversity, University of Wisconsin-Green Bay.

Submitted by **STEVEN J. PRICE** and **JEANETTE M. JASKULA**, Cofrin Center for Biodiversity MAC 212, University of Wisconsin-Green Bay, 2420 Nicolet Rd., Green Bay, Wisconsin 54311, USA.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander) **TERRESTRIAL MICROHABITAT.** Although *Hemidactylium scutatum* spends the majority of its life on the forest floor, few studies have focused on their terrestrial microhabitat preferences outside of the nesting season. Between August and late October 2001, we located *H. scutatum* during the day by searching 10 m^2 quadrats in a mature upland conifer forest at Toft Point State Natural Area in Door County, Wisconsin, USA (T30N R28E Sec 16). Each quadrat was searched for 15 min by both researchers and consisted of investigating cover objects (coarse woody debris, leaf litter, rocks, and decaying stumps). Once a specimen was found, we recorded the vertical position of the salamander (subsurface, surface under shelter, or exposed), the substrate immediately below the salamander (moss, soil, decaying wood, or leaf litter), and other amphibian species present within the quadrat.

Searches of 105 quadrats revealed the presence of 22 *H. scutatum*. Twelve (55%) were found on the surface under shelter, 8 (36%) were found beneath the soil surface, and only 2 (9%) were found exposed on the surface. Most subsurface encounters occurred when examining the contents of rotten stumps. The substrate directly beneath 10 (45%) salamanders was organic soil, decaying wood was found under 5 (23%), leaf litter under 4 (18%) and moss under 3 (14%). Other amphibians found during surveys included *Pseudacris crucifer*, *Rana sylvatica*, *Ambystoma laterale*, and *Plethodon cinereus*. The Chi-square test of independence (a = 0.05) revealed that *H. scutatum* was positively associated with all species except *Plethodon cinereus*. Our research supports the observations of Schaaf and Moore (1969. J. Herpetol. 3:180), Vogt 1981. Natural History of Amphibians and Reptiles of Wisconsin. Milwaukee Public Museum) and others, which suggest that *H. scutatum* spends its time outside the breeding season beneath cover objects on the forest floor or becomes fossorial. The Cofrin Center of Biodiversity, University of Wisconsin-Green Bay funded this research.

ANURA

BUFO FOWLERI (Fowler's Toad). **PREDATION**. In Canada, *Bufo fowleri* occurs in three disjunct populations (Rondeau, Long Point, and the Eastern Basin, largely encompassed by Niagara County). This disjunct distribution and fluctuations in abundance have resulted in the Committee on the Status of Endangered Species (COSEWIC) listing *B. fowleri* as a Threatened species. As a Threatened species, knowing potential sources of predation is especially important. Here we report the predation of a juvenile *B. fowleri* by two Ring-Billed Gulls (*Larus delawarensis*) in James N. Allan Provincial Park, Ontario, Canada within the Niagara region (N42.848 W079.664).

During the late afternoon of 16 Aug 2003 while conducting a

survey of toadlet abundance along the park beach, we observed a pair of Ring-billed Gulls on the beach pulling at a juvenile toad. When the gulls were disturbed, they flew out ca. 20 m into Lake Erie where the toad was dropped. The gulls landed beside the toad and swallowed it.

To our knowledge, this is the first reported predation of *B. fowleri* by gulls. Estimating the occurrence and sources of predation for such a threatened species has important conservation and management ramifications. We thank the Ontario Ministry of Natural Resources, and Ontario Parks for permission to conduct research and David Judd for his hospitality in the field.

BUFO OCELLATUS (NCN). **DEATH FEIGNING**. Death feigning or thanatosis (Edmunds 1974. Defense in Animals. Longman, New York, 357 pp.), is a common behavior among frogs (Sazima 1974. J. Herpetol. 8:376–377; Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill, New York; Azevedo-Ramos 1995. Rev. Bras. Biol. 55:45–47). On 7 Aug 2003, in Unaí municipality (46°7'W, 16°9'S) when handling an adult male *Bufo ocellatus* (42.8 mm SVL), we observed death feigning behavior in this species. The specimen adopted a motionless posture, keeping his limbs close to the body and eyes closed. After 45 sec. in this position, the frog started moving, attempting to escape. However, when restrained it reinflated the lungs and released bladder liquid. Both behaviors are similar to those described for *B. paracnemis* (Zamprogno et al. 1998. Herpetol. Rev. 29:96–97) and probably are widespread among other species of this genus. The function of death feigning may be related to increasing the chances of being lost by a predator and/or to minimization injuries when seized by a predator (Sazima, *op. cit.*).

A voucher specimen (AAG-UFU 2484) is housed in the Museu of Biodiversidade do Cerrado, Universidade Federal de Uberlândia, Minas Gerais, Brazil. We thank Ariovaldo A. Giaretta for critically reading the manuscript and the owners of the Fazenda Sagres S. A. for logistic support.

CHIASMOCLEIS VENTRIMACULATA and ***HAMPTOPHRYNE BOLIVIANA*** (NCN). **EFFECT OF PECCARY-HUNTING ON BREEDING HABITATS.** Anthropogenic influences on amphibian population declines can be categorized as direct habitat degradation and large-scale environmental changes (Blaustein et al. 1994. Conserv. Biol. 8:60–71; Dunson and Wyman 1992. J. Herpetol. 26:349–352; Fellers and Drost 1993. Biol. Conserv. 65:177–181; Harte and Hoffman 1989. Conserv. Biol. 3:149–158; Lind et al. 1996. Herpetol. Rev. 27:62–65).

The microhylid species *Chiasmocleis ventrimaculata*, *Ctenophryne geayi*, and *Hamptophryne boliviana* are sympatric throughout their western range, the Upper Amazon Basin of Ecuador and Peru. Since 1977, ecological data were gathered at the Peruvian Field Station Panguana where temporal blackwater ponds are typical spawning places for these species. At a large pond ca. 1200 m^2 spawning is coincident with an increase in precipitation followed by a short rainless period at the beginning of the rainy season. In addition to this pond there are small water-filled depressions, some of them muddy puddles used by collared and white-lipped peccaries (*Tayassu tajacu* and *T. pecari*) throughout the year. Like pigs, these peccaries are always moving in search of food and water, leaving the ground churned. They often return to the same mud wallows. Both species consume a wide range of food including fruit, roots, mushrooms, insects, snails; they occasionally feed on small vertebrates, e.g., lizards, snakes, frogs, and turtles. Their presence in a certain area is episodic and unpredictable. At Panguana *T. tajacu* is more common than *T. pecari* (Hutterer et al. 1995. Ecotropica 1:3–20).

These peccaries are eminent landscape architectures, increasing the diversity of aquatic plant and animal species. Anthropogenic influences on the herpetofauna of Panguana has been observed for a couple of years. One observation is the disappearance of many of the small temporary ponds, which can be caused directly by clearing woodlands or indirectly by hunting peccaries. Two of the small breeding ponds of *Hamptophryne boliviana*, *Chiasmocleis ventrimaculata*, and probably *Ctenophryne geayi* have disappeared. These ponds, known by the author since 1977, have formerly been puddles frequently used by peccaries. Since about 1992 footprints could not be found and the depressions gradually disappeared.

At the Río Pachitea and its confluence both peccaries are widely hunted, comprising a major part of daily proteins and skins (Redford and Robinson 1987. Am. Anthropol. 89:650–667). Detailed investigations are necessary to understand how this local hunting pressure depleting peccary populations affects amphibians and their reproduction. Similar studies will be necessary on tapirs (*Tapirus terrestris*) as amplecting pairs and egg clutches of *Hamptophryne boliviana* could be found in water-filled trails of peccaries and tapirs (Schlüter 1984. Doct. Dissert. Univ. Hamburg).

I thank the Instituto National de Recursos Naturales and Jesús H. Córdova (MHNSM) for their generous cooperation. Hans-Wilhelm Koepcke and his daughter Juliane Diller provided an opportunity to continue investigations on the herpetofauna of Panguana, and Gunther Köhler provided comments on the manuscript. Fieldwork was partly supported by the Förderverein of the SMNS and the Deutsche Forschungsgemeinschaft (DFG).

COLOSTETHUS DEGRANVILLEI (Degranville's Rocket Frog). **REPRODUCTION**. While photographing *Colostethus degranvillei* in French Guyana, Cacao in a village 80 km from the capital Cayenne (4°33'32"N, 52°28'11"W), 500 m elev., 7 June 1999 (1415 h), we observed three small frogs on the back of an adult frog. When first observed we thought these were small tad-

poles. The small frogs were dark brown with small blue dots. When disturbed, the small frogs would remain on the back of the parent. This suggests the tadpoles were normal, non-feeding larvae and they likely remained on the back of the male through metamorphosis. This area was very humid with normal temperatures around 30ºC this time of year, at the end of the rainy season.

This observation represents a new mode of reproduction not previously reported (Duellman and Trueb 1985. Biology of Amphibians. Johns Hopkins Univ. Press, Baltimore and London).

Submitted by **HUGH CLASSEN, JAN VAN DER MEULEN**, and **RONNY DE PAEPE**, Belgian Herpetological Society, Arthur Sterckstraat 18, B-2600 Berchem, Belgium; e-mail (HC): phyllos@online.be.

LEPTODACTYLUS MYSTACINUS (Mustached Frog). **DEIMATIC BEHAVIOR**. Deimatic behavior is a mechanism of secondary defense, which has the function of increasing the possibility of survival of an animal after it has been detected by the predator (Robinson 1969. Evol. Biol. 3:225–259). This behavior has been described in Leptodactylidae, especially *Pleurodema* and *Physalaemus* (Martins 1989. J. Herpetol. 23:305–307 and references therein). However, little is known about its occurrence in the genus *Leptodactylus*. *Leptodactylus mystacinus* is broadly distributed in eastern Brazil (Frost 2002. Amphibians Species of the World: an online inference 2:21). Herein, I report deimatic behavior of *L. mystacinus* collected in Nanuque City, Minas Gerais State, southeastern Brazil, on 4 Nov 2001, during faunal rescue activities for Hidroeletric Usine of Santa Clara (UHE Santa Clara - 17°53'S, 40°11'W). This locality is an extension of the geographic distribution of this species and the first occurrence in the Mucuri River Basin. When collected, the specimen exhibited a defensive position similar to that of *Physalaemus nattereri*. The first stage consisted of inflating the lungs, followed by lowering of the back and suspending the posterior region of the body. During this display, the forelegs remained close to the body. This posture makes it difficult for capture by predators and allows the individual to use its head or legs for defense (Sazima and Caramaschi 1986, *op cit.*). The individual remained in this position for only a few seconds. When again threatened, the individual abandoned the deimatic behavior and fled, seeking shelter. This species lacks well-developed and conspicuous inguinal glands. Glandular secretions were not observed. This behavior has also been observed in *Physalaemus fuscomaculatus* and *P. deimaticus*, although its functional significance is not well understood. A voucher specimen is deposited in the Reference Herpetologics Collection of the Pontifícia Universidade Católica de Minas Gerais (MCNAM 2636).

I thank the Companhia Energética Santa Clara for financial support, the Instituto Brasileiro de Meio Ambiente e dos Recursos Naturais Renováveis for collecting permits, Msc. Conrado A. B. Galdino for help, and Dr. Renato N. Feio for suggestions and comments on this manuscript.

MERTENSIELLA LUSCHANI (Luschan's Salamander). **ENDOPARASITES.** *Mertensiella luschani* is a salamandrid that is known from the mountains of southeastern Anatolia, Turkey, and the Aegean islands of Karpathos, Saria, and Kasos (Frost [ed.] 1985. Amphibian Species of the World: A Taxonomic and Geographical Reference. Published as a joint Venture of Allen Press, Inc. and The Association of Systematics Collections, Lawrence, Kansas. 732 pp.). To our knowledge, there are no reports of helminths from *M. luschani.* The purpose of this note is to report two species of Nematoda from *M. luschani.*

Fifty *M. luschani* (mean SVL 141 mm ± 22 SD, range: 85–175 mm) were collected August 1997 and April 2001 in Antalya, Turkey (36°52'N, 30°45'E, elev. 150 m). Salamanders were preserved in 10% formalin and stored in 70% ethanol. The esophagus, stomach, and small and large intestines were opened and separately examined for helminths under a dissecting microscope. Nematodes were cleared in a drop of concentrated glycerol and studied as a temporary wet-mount under a compound microscope. Two species of Nematoda were identified: *Angiostoma aspersae* (from the small intestine) and *Cosmocerca longicauda* (from the large intestine). Prevalence (number of infected salamanders/salamander sample x 100) and mean intensity (mean number helminths per infected salamander ± 1 SD and range) were: *A. aspersae* (34%, 1.3 ± 0.77 SD, range: 1–4); *C. longicauda* (3.0 ± 2.0 SD, range: 1–7). Selected nematodes were deposited in the United States National Parasite Collection, Beltsville, Maryland as *A. asperase* (USNM 94459) and *C. longicauda* (USNM 94460). Voucher salamander specimens were deposited at Uludag University, Department of Biology, Bursa, Turkey.

Angiostoma aspersae was originally described from specimens taken from the snail *Helix aspersa* collected in France (Morand 1986. Bull. Mus. Nat. Hist. Nat, Paris, 4e sér., A 11:111–115). *Mertensiella luschani* is the first salamander species reported to harbor *A. aspersae*; but more work is necessary to determine if this nematode directly infects salamanders or is only a byproduct of diet. *Cosmocerca longicauda* has previously been reported from other European salamandrids: *Triturus alpestris, T. cristatus, T. helveticus, T. montandoni, T. vulgaris* (Baker 1987. Mem. Univ. Newfoundland, Occas. Pap. Biol. 11:1–325). It is apparently palearctic in distribution. *Angiostoma aspersae* and *Cosmocerca longicauda* in *M. luschari* are new host records; Turkey is a new locality record.

PHYSALAEMUS BILIGONIGERUS (False-eyed Frog). **ENDOPORASITES.** Here we present data on helminths infecting *Physalaemus biligonigerus*. The study was carried out in a soybean cropland of the middle region of Argentina (31º14'46"S, 63º33'8"W, Córdoba Province) during December 2002 to March

2003. We collected 19 adult *P. biligonigerus* (7 males and 12 females; SVL 35–36 mm ± 1.96 mm).

All frogs were infected by helminths. The number of helminth species per individual host varied from 1–3 (most frequently three) and was not related to frog size (SVL, r = 0.22; p = 0.85). Three helminth species were recovered: one acanthocephalan, *Acantocephalus lutzi*, and two nematodes, *Rhabdias* sp., and *Physaloptera* sp. (found only as larvae cysts). Voucher specimens were deposited at the Faculty of Biochemistry and Biological Sciences Parasite Collection (FBCBPC 1000-3). Data on prevalence and infection intensities (*sensu* Bush et al. 1997. J. Parasitol. 83:575–583) for each helminth species and their respective sites of infection are given in Table 1. *Physalaemus biligonigerus* represents a new host record for *Acanthocephalus lutzi* and for the genera *Physaloptera* and *Rhabdias*.

Although the sample size is small, our data suggest that the population of *P. biligonigerus* that inhabited soybean cropland has a relatively high frequency of helminth infection, with the nematode *Physaloptera* being most prevalent. Stress, in the form of pesticide exposure, may decrease the host amphibians' ability to resist infection, resulting in higher parasite loads (Kiesecker 2002. Proc. Natl. Acad. Sci. 99:9901–9904). Despite the risk, anuran populations in the midwestern Córdoba Province coexist with soybean crops that are the dominant land use in this region. In addition, these anurans are exposed to pesticides used to protect these crops. Further studies are necessary to confirm the relationship between pesticide exposure and parasite infection.

We thank Graciela Navore and Mónika Hamann for suggestions.

TABLE 1. Prevalence (in percentage and absolute values) and intensity of infection (mean ± standard deviation, with range in parentheses) of helminths found in *Physalaemus biligonigerus* (N = 19).

	Helminth Prevalence	Mean intensity (range)	Site of infection
Acanthocephala			
Acanthocephalus lutzi	26.32% (5)	5 ± 3.5 (2–10)	Intestines
Nematoda			
Rhabdias sp	36.84% (7)	5 ± 3.8 (2–13)	Lungs
Physaloptera sp. (larvae)	84.21% (16)	28.7 ± 17.6 (3–50)	Stomach, cysts

RANA BOYLII (Foothill Yellow-legged Frog). **PREDATION**. Introduced aquatic predators are known to negatively effect amphibian populations both directly and indirectly (Kats and Ferrer. 2003. Diversity and Distributions 9:99–110). The Signal Crayfish (*Pacifastacus leniusculus*) is native to the Pacific Northwest and has been introduced into numerous Sierra Nevada drainages which are currently populated by *R. boylii* including the Pit, Stanislaus, South Fork Trinity (Jamie Bettaso, pers. comm.), and the North Fork Feather rivers. Failed recruitment at several *R. boylii* breeding sites on the Pit River led to speculation about possible negative impacts of the signal crayfish on *Rana boylii* populations (Pacific Gas and Electric Company, unpubl. data).

In conjunction with visual encounter surveys on the regulated Cresta Reach of the North Fork Feather River (Butte Co., California), we installed an Aqua Vu® underwater video camera system to monitor *R. boylii* egg masses and tadpole groups.

Analysis of over 92 hours of videotape revealed several predation events upon a *R. boylii* egg mass. On 23 June 2003 at 1819 h an adult *P. leniusculus* was observed feeding on a *R. boylii* egg mass (depth 21 cm; water temp 16°C; distance from shore 80 cm; 0636000 N, 4410200 E; NAD 27, Zone 10; 427 m elev.). During this observation the crayfish exhibited defensive behavior when another adult crayfish approached and appeared to initiate feeding, and was successfully driven off. Periodic feeding continued by the defending crayfish (entire event lasted 19.2 minutes; video verified by L. Kats), and recently hatched larvae were observed fleeing the egg mass during feeding. *Pacifasticus leniusculus* was commonly observed near egg masses and tadpole groups during video monitoring in both diurnal and nocturnal conditions.

During visual encounter surveys, we noted at least three observations of larvae with tail injuries suggestive of predation attempts by crayfish (injuries resembled clean, scissors-like cuts). Larval tail injuries have also been noted by other biologists working on the Poe Reach of the North Fork Feather River (A. Pool, pers. comm.). These observations are consistent with studies showing that Signal Crayfish are adept at consuming anuran larvae using their claws and walking legs, with unsuccessful prey handling resulting in tail loss (Axelsson et al. 1997. Amphibia-Reptilia 18:217–228). Our observations of Signal Crayfish depredating and molesting *R. boylii* egg masses suggest that they might also contribute to the dislodging of egg masses, leaving them vulnerable to further losses associated with river flow fluctuations.

We also observed a predation attempt upon a *R. boylii* larva. On 27 June 2003 at 2059 h an undetermined species of young-of-the-year fish (ca. cyprinid) attempted to consume a recently-hatched *R. boylii* larva (depth 18 cm; water temp. ca. 14°C; distance from shore 160 cm; 0636281 N, 4411255 E; NAD 27, Zone 10; 427 m elev.). The outcome of this observation remains uncertain because of low light conditions and unclear movements of the larva after the fish captured it in its mouth. During this observation other young-of-the-year fish were observed pecking the substrate in the area where several hundred recently-hatched *R. boylii* larvae were located.

Studies conducted in Europe showed that the presence of exotic *P. leniusculus* caused tail injuries, decreased metamporph size and survivorship of *Rana temporaria* (Nyström et al. 2001. Ecology 82:1023–1039). Recent work conducted in the Sierra Nevada has demonstrated that *P. leniusculus* is more likely to be found in close

proximity to reservoirs and in regulated vs. unregulated systems (Light 2003. Freshwater Biol. 48:1886–1897). Preliminary analysis of 328 historical *R. boylii* localities within the entire range shows that 90 (27.4%) of the localities have a dam of any size upstream and 67 (20.4%) have at least one large dam (>15 m high) upstream (A. Lind, unpubl. data). These data suggests that a significant proportion of *R. boylii* populations may be vulnerable to impacts caused by introduced Signal Crayfish. Recent observations by Rombough and Hayes (2005. Herpetol. Rev. 36:163–164) describe Signal Crayfish preying upon the embryos of *R. boylii* within the natural range of the crayfish. This indicates that historically, northern populations of this frog have had some experience with crayfish predators.

Further studies should address: 1) other possible indirect effects of *P. leniusculus* on *R. boylii* populations such as changes in larval behavior, development, and survivorship, 2) the extent of Signal Crayfish distribution within the range of *R. boylii*.

A condensed version of the video clip can be viewed at: http://www.garciaandassociates.com/sanfran.htm. We thank Pacific Gas and Electric Company biologists A. Pool, C. Seltenrich, W. Roberts, C. Herrala, and M. Carbiener for helpful advice and assistance under the FERC 1962 project; J. Minton for assistance with field work and camera system configuration; L. Kats for review of video; A. Lind for helpful advice and information.

RANA BOYLII (Foothill Yellow-legged Frog). **PREDATION: EGGS AND HATCHLINGS**. Direct observations of predation on eggs and embryos of North American ranid frogs exist (Chivers et al. 2003. Oikos 92:135–142; Evenden 1948. Copeia 1948:219–220; Rathbun 1998. Herpetol. Rev. 29:165; Saenz et al. 2003. Copeia 2003:646–649), but the typical brevity of such events often results in inferring their occurrence (e.g., Howard 1978. Ecology 59:789–798; Van Wagner 1996. Selected Life History and Ecological Aspects of a Population of Foothill Yellow-legged Frogs (*Rana boylii*) from Clear Creek, Nevada City, California. MSc Thesis, California State University, Chico, California. 143 pp.). Further, smaller size and poorly developed predator-evasion ability make hatchling ranid frog larvae vulnerable to a larger predator set than older larvae (Licht, *op. cit.*). Despite this larger array of predators, hatchling mortality, like egg mortality, is also often inferred, typically from a rapid decline in numbers during the immediate post-hatching period (e.g., Calef 1973. Ecology 54:741–758; Licht 1974. Can. J. Zool. 52:613–627). Such data underscore the belief that aquatic larvae sustain the greatest mortality among ranid frog life stages (e.g., Calef, *op. cit.*; Cecil and Just 1979. Copeia 1979:447–453; Herreid and Kinney 1966. Ecology 47:1039–1040; Licht, *op. cit.*). For these reasons, we provide direct observations of predation on both the eggs and hatchling larvae of *Rana boylii* from Oregon, USA.

During a survey of *R. boylii* oviposition sites during 16–30 May 1997, one of us (MPH) made observations of egg predation at two different sites along the South Umpqua River east of Tiller (Douglas Co., Oregon). At the first site, 9 *R. boylii* egg masses were located on a bedrock shelf in shallow (< 25 cm) water, and were attached to both the downstream side of cobbles or boulders (N = 6) and to the margin of a flow-protected bedrock crease (N = 3). Flow velocities adjacent to egg masses were 0.5–0.8 m/sec. An adult (ca. 100–110 mm TL) Signal Crayfish (*Pacifastacus leniusculus*), native regionally, was seen next to each of two of these egg masses. At one egg mass, MPH observed a crayfish use its mouthparts and anterior walking legs to manipulate a 3-cm lobe of the egg mass gently oscillating in the current about 4 cm above the substrate. Over a 10-min interval, the crayfish removed and ate three embryos (ca. Gosner Stage 11) before being attracted to detritus drifting nearby. Examination of the area where the crayfish had fed revealed five torn egg capsules, four with missing embryos and one with a 1-mm fragment of an embryo. A second adult crayfish was first observed moving over the substrate near one of the egg masses in the bedrock crease. When the crayfish, approaching from downstream, got within 10 cm of the mass, it changed direction, moved directly to the egg mass and began to pull at an elongate, partly torn lobe. In less than a minute, the crayfish had torn off a piece of the lobe containing 15–20 eggs and retreated into the bedrock crease, where it continued to pick at and tear the jelly with its walking legs. Six embryos were seen removed from the jelly over a 20-min period before observations were discontinued. Although most was discarded, the crayfish also consumed some capsular jelly. At the second site, five *R. boylii* egg masses were seen attached to bedrock near the base of a 0.5-m cascade; flow velocities near the egg masses were 0.7–1.1 m/sec. During examination of these masses, MPH observed another crayfish move upwards through a 3–4 cm crease in the bedrock partly covered by two of the egg masses, both with embryos in tail bud stage (Gosner Stage 17). The crayfish moved into a semi-concealed position between the egg masses and proceeded to pull at the jelly of the lower mass with its anterior walking legs. During 35 min of observation, the crayfish opened eight capsules, successfully extracting seven embryos, and was still picking at the jelly when observations were discontinued.

In the course of a study of *R. boylii* during 2000–2003, CJR made a series of observations along the South Santiam River, 10 km E of Sweet Home (Linn Co. Oregon; 44°25'N, 122°34'W; elev. 192 m). Site geology is distinctive; erodable conglomerates within hard competent tuffs result in a relatively flat bedrock surface scoured bare of almost all loose rock < 0.5 m in diameter and within which exists a series of troughs and scour pools holding mostly smaller cobble and gravel. All observations occurred during the interval after oviposition (June–early July), when river width is 100–120 m and water depth at marginally located oviposition sites is ca. 30 cm.

On 27 June 2000, a 30-mm (total length) pebble-case caddisfly larva (*Dicosmoecus gilvipes*) was observed crawling on the surface of a *R. boylii* mass (Gosner stage 14). The caddisfly was seen to grasp each capsule with its legs, turn it over and repeatedly probe into the jelly with its mandibles. During this manipulation of at least four different eggs, CJR saw the larva thrust its mandibles through the jelly, reach the embryo, and chew it for a few seconds before withdrawing its head from the capsule. The caddisfly larva reached four embryos, but it ate less than one-third of the most-chewed embryo during 5 min of observation. On 4

June 2003, a similar-sized *D. gilvipes* larva was observed burrowing through the jelly of a *R. boylii* egg mass (Gosner Stage 11) using its legs and mandibles. In contrast to the aforementioned larva, this larva chewed a path directly toward an embryo. On reaching the embryo, it consumed the embryo entirely, leaving an empty capsule and then moved to another egg. In ca. 5 min, the *D. gilvipes* larva had eaten at least three embryos. On seven other occasions, similar-sized *D. gilvipes* larvae were seen probing the surface of *R. boylii* egg masses with their mandibles; in one instance, a larva was observed with a *Rana boylii* egg mass fragment containing 50 embryos attached to its pebble case.

During 8 min of observation on 11 July 2000, seven (five ca. 60 mm fork length (FL) and two ca. 20 mm FL) Speckled Dace (*Rhinichthys osculus*) and one Reticulate Sculpin (*Cottus perplexus*; ca. 60 mm FL) were observed picking *R. boylii* hatchlings (Gosner Stage 20) from the surface of an egg mass and nearby cobble substrate. The mass, in a 30-cm deep pool with low flow (< 1 m/sec), had an indirect connection (> 20 cm depth) to the river. The larger fish typically swallowed *R. boylii* hatchlings whole, one plucking several larvae from within the jelly, but the two smaller dace only picked at the hatchlings. On the same date, ca. 50 m upstream, CJR observed another mixed-species group of 15 cyprinid fishes (including dace, Northern Pikeminnow [*Ptychocheilus oregonensis*], and Redside Shiner [*Richardsonius balteatus*]), all ca. 60 mm FL, capturing hatchling *R. boylii* (Gosner Stage 22) larvae in a similar manner around three egg masses in a shallow (ca. 8 cm deep) pool with a ca. 10 cm deep connection to the river. A school of > 100 smaller (10–15 mm FL) cyprinid fry were also in the pool, but were not seen attempting to prey on *R. boylii* larvae.

On 6 June 2003, CJR observed five (40 mm FL) dace and a sculpin (80 mm FL) feeding on the eggs and jelly of a recently laid (Gosner Stage 4) *R. boylii* egg mass in water 19 cm deep. Predatory behavior was similar to the previous accounts, except that both the dace and sculpin picked off and consumed bits of jelly in addition to eating any embryos that became exposed. Several embryos and some of the surrounding jelly were eaten in this manner over 4 min of observation.

On 12 June 2003, CJR observed a mixed-species school of about 60 (30–50 mm FL) cyprinid fishes (mostly dace, but also Northern Pikeminnow and Redside Shiner) feeding on the aging jelly of an *R. boylii* egg mass and its (Gosner Stage 20) hatchling larvae. The ca. 20 cm deep pool in which this egg mass was located was almost completely disconnected from the active channel. Many larvae had emerged from the mass; these larvae both clung to the sides of the mass and settled into interstitial spaces in the surrounding cobble, from which the fish were picking them. At least 10 *R. boylii* hatchlings were consumed during 10 min of observation.

In addition to these observations of predation, all four fish species described herein were documented in *R. boylii* oviposition pools on > 11 other occasions (at least one of which involved direct predation of *R. boylii* embryos) when *R. boylii* egg masses were present.

Previous to our observations, the only published report of unambiguous predation on eggs of *R. boylii* is that of Evenden (*op. cit.*), who removed eggs from the stomachs of some of 35 Rough-skinned Newts, *Taricha* [as *Triturus*] *granulosa*, from the South Santiam River (Oregon). Wiseman et al. (2005. Herpetol. Rev. 36:162–163) also documented Signal Crayfish predation of *R. boylii* eggs from within the introduced range of this crayfish in northern California. In contrast, no previous reports of hatchling predation exist.

Oregon Department of Fish and Wildlife provided funding for CJR, and the US Forest Service provided logistic support for CJR and funding for MPH; this work represents a contribution from the Science Division of the Habitat Program of the Washington Department of Fish and Wildlife. Permits to handle *R. boylii* were issued by the Oregon Department of Fish and Wildlife.

RANA BOYLII **(Foothill Yellow-legged Frog). PHYSIOLOGICAL SKIN COLOR TRANSFORMATION.** Color change as well as lightening and darkening of skin tones have been documented in several anurans (King et al. 1994. Copeia 1994:422–432; King and King 1991. Can. J. Zool. 69:1963–1968). Nussbaum et al. (1983. Amphibians and Reptiles of the Pacific Northwest. Univ. Idaho Press, Moscow, Idaho. 332 pp.) reported that individual *Rana boylii* are capable of lightening and darkening, however, we are unaware of any detailed documentation of this phenomenon in this species. The anuran dermis layer contains three types of chromatophores that may be responsible for pigment change: iridophores, xanthophores, and melanophores. Melanophores are the pigment cells responsible for lightening and darkening of the skin. This skin tone change is the most common color transformation documented in anurans. Here we report a field observation of skin color transformation in *R. boylii*. *Rana boylii* is a stream-breeding frog that reputedly dwells almost exclusively along running waters where it is associated with both in-stream and stream margin habitats. However, we often find frogs on adjacent uplands such as gravel bars and moist vegetated areas within the floodplain (unpubl. data). *Rana boylii* are heliotherms that thermoregulate by basking on heated surfaces such as sun-warmed rocks. On 16 Oct 2003 at ca 1040 h during a survey on Hurdygurdy Creek, Del Norte County, California, USA, we captured an adult female *R. boylii* (52 mm SUL) on an upland floodplain area 5.5 m from the wetted edge. The primary substrate was cobble and recent rains had produced a newly fallen moist leaf litter layer. The frog was found sitting in a shady spot on top of yellowish leaf litter. We measured, weighed, and pit-tagged the frog and took a photo of the ventral side of the frog's chin (Fig. 1). We have been routinely collecting photos of frog chins to determine if the mottling patterns on their chins can be used to identify individual frogs. In addition, we took a full body photo because this frog had a very distinct, nearly white, pale tan color (Fig. 1). *Rana boylii* dorsal skin coloration can be highly variable (light gray, olive green, brown, brick red); however, of 196 captured and marked adult frogs (>40 mm SUL) at our study site over the last two years, this particular frog was noticeably lighter in color than any other we

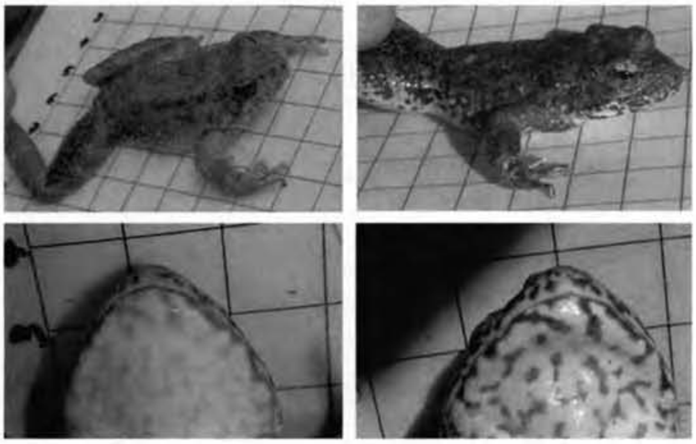

FIG. 1. Dorsal body and ventral side chin photos of the captured *Rana boylii*. Photos in the left column were taken at initial capture (1040 h). Photos in the right column were taken at second capture (1300 h).

have captured. Her chin mottling was very faded as well.

At ca. 1300 h when returning from the completed survey we captured an adult female frog ca 2.5 m from the location of the previously mentioned frog. The frog was sitting in a shallow silt-bottomed puddle surrounded by dark colored cobbles on the same upland floodplain area. Because this frog was nearly black in color, we initially assumed it to be a new capture. Upon closer inspection, the frog was newly pit-tagged and upon reading the pit-tag we discovered it was the same frog captured earlier in the survey. We immediately re-photographed her full body and chin (Fig. 1), and took additional photos 15 min and 1.5 h later when both body color and chin mottling color were subsequently paler, although not as pale as the initial capture. Our observations indicate that *Rana boylii* can undergo relatively rapid color transformations, changing from light to dark shades and back to light shades. The cue that prompts this color darkening and lightening and the function of the change is unknown. Because of the numerous variables between captures of this individual (background substrate, photoperiod, temperature, time since disturbance), we cannot speculate on the stimuli or the function of the observed changes.

We thank Sharyn B. Marks for providing comments on an earlier draft of this manuscript.

Submitted by **CLARA A. WHEELER** (e-mail: cawheeler@fs.fed.us), **JUSTIN M. GARWOOD**, and **HARTWELL H. WELSH, JR.**, Redwood Sciences Laboratory, 1700 Bayview Drive, Arcata, California 95521, USA.

RANA CASCADAE (Cascades Frog). **PREDATION.** Many potential predators of *Rana cascadae* have been reported, however no studies have actually documented predation by the garter snakes, *Thamnophis atratus* and *T. sirtalis*. During a radio telemetry study of *R. cascadae* within the Trinity Alps Wilderness, Trinity County, California, USA, we confirmed predation on three adult *R. cascadae* and suspect another by these garter snakes.

On 23 June 2003 we palped a radio-tagged adult male *R. cascadae* (22.5 g, 58 mm SUL) that had been tracked for the previous 3 days from an adult *T. atratus* (850 mm TL). On 12 Aug 2003 we palped a radio-tagged adult female *R. cascadae* (30.7 g, 71 mm SUL) that had been tracked for the previous 26 days from an adult *T. sirtalis* (720 mm TL). On 25 Aug 2003 we palped a radio-tagged adult female *R. cascadae* (24.5 g, 61 mm SUL) that had been tracked for the previous three days from an adult *T. sirtalis* (700 mm TL). From 1–5 Sept 2003, out of five tracking attempts, we could not visually locate a radio-tagged female *R. cascadae* (22.3 g, 58.9 mm SUL) that had been tracked for the previous 25 days. Strong signals were coming from terrestrial bank burrows ca. 2 m from water. Subsequently, on 07 Sept 2003 we found the transmitter along with its attachment ribbon, both were coated with a slimy film. It is likely this individual was also eaten by an adult *Thamnophis* sp. All three confirmed predation events occurred near lentic water bodies, where *R. cascadae* reproduction was documented in 2003 (J. Garwood, unpubl. data). On 23 Sept 2003 we observed an adult *T. sirtalis* capturing and eating *R. cascadae* tadpoles by herding groups of them into small shallow alcoves of a pond. On 13 Oct 2003 we observed a subadult *T. sirtalis* (ca. 450 mm TL) probing its head into cracked mud interstitial areas at a dry pond. The interstitials within the mud contained hundreds of recently metamorphosed *R. cascadae* and *Hyla regilla* taking refuge. We observed one predation event of a post-metamorphic *R. cascadae* by this snake.

These observations of predation document that *T. atratus* and *T. sirtalis* prey on larval, metamorph, and adult *R. cascadae*. These snakes were seen regularly during our telemetry study and we suspect they are a major predator of *R. cascadae*.

We thank Clara Wheeler, Ryan Bourque, and Terra Fuller for field assistance.

WELSH, JR.**, Redwood Sciences Laboratory, 1700 Bayview Drive, Arcata, California 95521, USA.

SCAPHIOPUS COUCHII (Couch's Spadefoot). **ENDOPARASITES.** Previous reports of endoparasites in *S. couchii* are the monogenean *Pseudodiplorchis americanus* (Tinsley and Earle 1983. Parasitology 86:501–517), the cestode *Distoichometra bufonis* and the nematodes *Aplectana incerta, A. itzocanensis*, and *Oswaldocruzia pipiens* (Goldberg and Bursey 1991. J. Helminthol. Soc. Washington 58:142–146; Tinsley 1990. Am. Zool. 30:313–324), all reported from Arizona. The purpose of this note is to report a new host record and new locality records for helminths in *S. couchii*.

Fourteen *S. couchii* (mean SVL 44.6 mm ± 12.2 SD, range: 27–60 mm) were collected from Cochise County, Arizona in 1972 (N = 10) or Pima County, Arizona in 1971 (N = 4). Eight *S. couchii* (SVL 50.3 mm ± 11.4 SD, range: 28–64 mm) were collected in Hidalgo County, New Mexico in 1972. Spadefoots were deposited in the Museum of Zoology, University of Michigan, Ann Arbor as UMMZ 230124–230137 (Arizona) and UMMZ 230138–230145 (New Mexico). The esophagus, stomach, small and large intestines, lungs, and urinary bladder were opened and separately examined for helminths under a dissecting microscope. The body cavity was also examined for helminths. Monogeneans and cestodes were regressively stained in hematoxylin and studied as

whole-mounts; nematodes were cleared in a drop of concentrated glycerol and studied as wet mounts.

Found from Arizona were one species of Monogenea *P. americanus* (urinary bladder) (prevalence: number infected spadefoots/sample examined x 100 = 7%, mean intensity ± 1 SD: mean number helminths per infected spadefoot and range = 1.0), two species of Cestoda *D. bufonis* (prevalence 29%, mean intensity 6.3 ± 5.0, 1–11) and *Nematotaenia dispar* (both small intestines; prevalence 14%, mean intensity 12.0 ± 5.7, 8–16) and two species of Nematoda *A. incerta* (prevalence 36%, mean intensity 100.8 ± 122.4, 2–305) and *A. itzocanensis* (prevalence 14%, mean intensity 46.5 ± 62.9, 2–91; both large intestines). Found from New Mexico were *P. americanus* (prevalence 38%, mean intensity 1.0) and *A. incerta* (prevalence 38%, mean intensity 62.0 ± 48.3, 23–116). Helminths were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland as: Arizona, *Aplectana incerta* (94447), *A. itzocanensis* (94448), *Distoichometra bufonis* (94445), *Nematotaenia dispar* (94446), *Pseudodiplorchis americanus* (94444); New Mexico, *A. incerta* (94451), *P. americanus* (94449–50).

Kuntz (1941. Proc. Oklahoma Acad. Sci.21:33–34) reported two species of cestodes from *S. couchii* but did not designate which species they were. *Nematotaenia dispar* is a new host record for *S. couchii;* New Mexico is a new locality record. *Pseudodiplorchis americanus* from New Mexico is a new locality record.

TESTUDINES

CARETTA CARETTA (Loggerhead Seaturtle). **PREDATION.** Documenting predation on hatchling seaturtles is important for population demographers when developing research and conservation strategies. Hatchling predation by crabs, raccoons, and other terrestrial species are well known. Unfortunately, most marine predators are seldom identified to species and are lumped into groups such as sharks and fish (Stancyk 1995. Biology and Conservation of Sea Turtles. Smithsonian Institution Press, pp. 139–152). Establishing the identity of fish species that consume *Caretta caretta* hatchlings off the southeastern coast of the United States is difficult because the turtles emerge and enter the surf at night, and determining the magnitude of the nocturnal predation is even more challenging. Stewart and Wyneken (2004. Bull. Mar. Sci. 74:325–335) produced the first study to address nearshore hatchling predation in the southeastern U.S. They reported tarpon (*Megalops atlanticus*) and catfish (*Arius felis*) as the major identified nearshore predators of hatchling Loggerheads (four each) at Juno Beach, Florida, as well as several unknown predators.

On 20 July 1998, a fishery observer aboard a shark gillnet boat 22.2 km NE of Cape Canaveral, Florida took photos of a crew member cleaning the catch of Atlantic Sharpnose Sharks (*Rhizoprionodon terraenovae*). The observer noted that several hatchling Loggerhead Seaturtles had been recently consumed in the three shark stomachs cut open. The three sharks had two hatchlings each. Unfortunately, because of the large number of sharks on board, no more stomachs were cut open because the sharks were being processed for market. These are small (< 80 cm), abundant sharks and frequently school near the Loggerhead nesting beaches in summer months (Dodrill 1977. Ph.D. dissertation. Florida Inst. Technol., Melbourne. 304 pp.). These sharks also occur further offshore near the edge of the Gulf Stream, where surface downwelling and strong northerly currents concentrate hatchling turtles in lines of *Sargassum* weed (Witherington 2002. Mar. Biol. 140:843–853). Earlier, Witham (1974. Copeia 1974:548) reported eight hatchling Loggerhead Seaturtles and one Green Seaturtle (*Chelonia mydas*) from the stomach of a dolphin fish (*Coryphaena hippurus*) captured near a patch of floating *Sargassum* weed 19 km E of the nesting beach at St. Lucie Inlet.

Stewart and Wyneken (*op. cit.*) felt that the nearshore predation rate was probably higher than the offshore predation rate because the predators are (hypothetically) concentrated on the reef line. However, the hatchlings are only subjected to a short period (ca. 15 min) of exposure as they move from the beach to deeper water at night. It is possible, however, that the predation rate in deeper water may be significantly higher than the nearshore predation rate because the *Sargassum* weed lines concentrate hatchlings into a narrow nektonic buffet for dolphin fish and sharpnose sharks for months.

GLYPTEMYS INSCULPTA (Wood Turtle). **JUVENILE MOVEMENTS AND HOME RANGE.** Here we report movements and home ranges of two juvenile *Glyptemys insculpta* in southern New Hampshire, including the longest-distance movements from streams reported for the species. Thirty-six juveniles (lacking secondary sexual characteristics as described by Harding and Bloomer [1979. Bull. New York Herpetol. Soc. 15:9–26]) were hand-captured and marked by marginal scute notching; age estimates were determined by counting growth annuli on the right abdominal scute. Age-0 hatchlings (N = 54) that emerged during the study period were not included as juveniles. Two juveniles, one from each of two convergent streams (Stream A, Stream B), were fitted with 18-g radio transmitters and located throughout the active season every other day from 8 April 1993 to 30 May 1994 (N = 66, N = 77 recaptures per turtle). Methods used for determining home ranges follow Tuttle and Carroll (2003. Chelonian Cons. Biol. 4:656–663).

An additional 34 juveniles (mean CL = 96.9 ± 34.4, range = 34.9–154.7 mm; mean number of annuli = 5.9 ± 3.8, range = 1–15; measurements are ± 1 SD) captured that were not affixed with radio transmitters were found either in a stream (N = 5) or within 70 m of a stream (mean = 15.7 ± 23.4 m, N = 29). Among younger age classes, first-year juveniles hatched in 1992 (N = 6) were found within 1.8 m of the water in dense vegetation bordering a stream; all 2-yr-old juveniles (N = 4) were found within 10 m of a stream.

Radio-tagged Juvenile #1 (CL = 143 mm, mass = 490 g, annuli = 11) occupied a small home range (0.7 ha, as calculated by the convex polygon method) in an area that included Stream B and the sloping edge of a hayfield that was located 60 m from the stream and that was separated from the stream by alder swamp

habitat and a dirt road. The juvenile traveled back and forth between the hayfield bank and the stream throughout the active season. Usually the turtle was found in dense grass cover or cryptically basking on top of the flattened grass where the height of the surrounding vegetation provided the turtle with cover. This juvenile entered hibernation on 4 October in water ca. 0.6 m in deep, within a few meters of its capture location on the stream bottom on 8 April.

Radio-tagged Juvenile #2 (CL = 122 mm, mass = 280 g, annuli = 8) had a convex polygon home range size of 27.6 h, which was comparable to the mean size of adult male home ranges (23.9 ha) in this population (Tuttle and Carroll 2003, *op. cit.*). Until 4 July, the turtle remained in or near Stream A most of the time, although it traveled long distances in the stream. Twice it was found on the edge of a hayfield ca. 150 m from water. By 9 July, Juvenile #2 had moved 0.5 km from the stream to its terrestrial summer range located in upland mixed forest where it was most often found hidden in piles of slash or dense successional vegetation at a crossroads of previously-used logging trails. During this period the turtle traveled as far as 865 m from the stream. Although Juvenile #2 returned to Stream A on 29 August, it did not enter hibernation until 19 October.

There was a 39-fold difference in convex polygon-calculated home range size between the two juveniles. Stream A was bordered by a large expanse of upland forest with a sparsely vegetated herbaceous layer. Suitable summer habitat that included disturbed areas near logging road junctions were located at much longer distances from Stream A. Conversely, Juvenile #1 had sufficient cover located within close proximity of Stream B. In contrast to Stream A, Stream B was bordered by 75% more alder swamp habitat containing rich organic soils where adult Wood Turtles were observed to forage for earthworms. Home ranges for adults along Stream B were generally smaller and more linear in shape, with the turtles remaining closer to the stream (Tuttle and Carroll 2003, *op. cit.*). Home ranges of telemetered juveniles from each of the two streams in our study fit a similar spatial pattern.

These data show that juvenile *G. insculpta* can occupy home ranges as large as 27.6 ha and use summer habitat as far as 865 m from a stream. Our results augment previously recorded movements and home range observations of *G. insculpta* and indicate that potentially long terrestrial movements and access to cover should be considered when planning conservation and management strategies for this species.

Submitted by **SHEILA E. TUTTLE,** Antioch New England Graduate School, Keene, New Hampshire 03431, USA; Present address: Department of Biology, Skidmore College, Saratoga Springs, New York 12866, USA; and **DAVID M. CARROLL**, Box 63, Warner, New Hampshire 03278, USA.

GLYPTEMYS (CLEMMYS) MUHLENBERGII (Bog Turtle). **PREDATION.** On 27 April 1986, during a study of a population of *Glyptemys muhlenbergii* in Sussex County New Jersey, USA, a predated and empty shell of *G. muhlenbergii* was located. On 23 September 1986 three additional predated, and empty, *G. muhlenbergii* shells were located, and one of the Common Snapping Turtle, *Chelydra serpentina*; all appeared to be fresh kills. Descriptions of the chelonians follow: *G. muhlenbergii*: 11 year old female SCL = 83 mm, plastron intact, head and limbs missing, heavy chew marks on anterior portion of carapace and plastron; 9-year old female SCL = 87 mm, plastron intact, head and limbs missing; 12-year old female SCL = 78 mm, plastron intact, head and limbs missing; 4-year old female SCL = 58 mm cracked carapace only, plastron missing. *Chelydra s. serpentina*: SCL = 71mm carapace only, plastron missing.

The four *G. muhlenbergii* represented 13.8% of the known population at that time. The habitat consists of a two hectare cow pasture crossed by intermittent small streams. All shells were located on the edges of these streams within one meter of waters edge. The predators had located the chelonians by rolling back mats of *Sphagnum* sp. and leaving the chelonians exposed. Numerous tracks of the Raccoon, *Procyon lotor*, were observed around each of the predated shells. The tracks were followed back to a brush pile, measuring seven meters in diameter and three meters high, of cut saplings of Red Maple, *Acer rubrum*, and Alder, *Alnus* sp., that the farmer had cut from the wetland and piled prior to removal from the area. Inspection of the brush pile located two sub-adult Raccoons, which were suspected to be the predators of the chelonians. This report should warn land managers and habitat rehabilitators against piling cuttings of cleared debris, even temporarily, which might create shelter for potential predators.

All shells have been deposited in the New Jersey State Museum: accession number MH2003.20. This study was performed under permit from The State of New Jersey dated 31 March 1986.

KINOSTERNON SONORIENSE (Sonoran Mud Turtle). **DIET**. Hulse (1974. J. Herpetol. 8:195–199) concluded from an examination of stomach contents that *Kinosternon sonoriense* was an opportunistic carnivore that fed mainly on invertebrates, though plants, fish, and ranid frogs were occasionally eaten. Ligon and Stone (2003. Herpetol. Rev. 34:241–242) reported two observations of *K. sonoriense* feeding on adult *Bufo punctatus*. Here, we add a reptile and a bird to the list of dietary items consumed by *K. sonoriense*. Both observations were made in small pools in the Peloncillo Mountains, Hidalgo Co., New Mexico (USA), in the same canyon as the observations reported by Ligon and Stone (*op. cit.*).

On 7 August 2004, at ca. 1000 h, we observed an adult female *K. sonoriense* (101.7 mm midline carapace length [MCL], 151 g) capture and kill a Black-necked Gartersnake (*Thamnophis cyrtopsis*, 348 mm SVL, 23.3 g). The observation began when we noticed splashing in a pool (ca. 12 m^2 area, ca. 10 cm deep) beside the trail. When first observed, the turtle's jaws held the snake by the neck, ca. 10 cm behind the snake's head. During the first 10 sec. of the encounter, the snake attempted to bite the turtle on the carapace at least twice. Within two minutes, the snake was dead and the turtle was eating the snake. At this point the turtle seemed to notice us and released the snake, moving away from us, toward the edge of the pool. We then captured and measured the turtle and collected the snake. The skin had been stripped off the dead snake from the point where the turtle had grasped the snake forward to the head, and there was a large piece of neck muscle missing. We released the turtle and deposited the snake in the Univer-

sity of Central Oklahoma Collection of Vertebrates (UCO 1001).

On 10 August 2004, at ca. 1800 h, we encountered an adult male *K. sonoriense* (114.5 mm MCL, 169 g) in a small pool (ca. 1 m^2 area, ca. 15 cm deep) with a dead Mockingbird (*Mimus polyglottos*). The intact, feathered head and wings of the bird were floating on the water surface. Below the water surface was the bird's skeleton, which had been picked nearly clean of soft tissue. The turtle had bird flesh on its face and foreclaws. After we identified the turtle, we photographed the bird and observed the turtle feeding on scraps of the bird that had settled to the bottom of the pool. We do not know how the bird died and are uncertain as to whether our observation involved predation or scavenging.

Mud turtles are common in shallow pools in our study area (Stone 2001. Southwest. Nat. 46:41–53). The obvious benefits of inhabiting these pools include hydration and opportunities to eat invertebrates, which are common in pools. Our observations, coupled with those of Ligon and Stone (*op. cit.*), suggest that pools might provide opportunities for mud turtles to eat relatively large vertebrates, and that vertebrates might be more important to the diet of *K. sonoriense* than previously thought.

We thank J. Hellack and W. Radke for identifying the bird from photographs. We thank the College of Graduate Studies & Research at the University of Central Oklahoma for financial support. This study was conducted under permits issued by the New Mexico Department of Game and Fish (Permit 2905) and the U.S. Forest Service (Authorization ID: SUP0080).

MACROCHELYS TEMMINCKII (Alligator Snapping Turtle). **AERIAL BASKING.** *Macrochelys temminckii* is generally believed to be largely aquatic, with only females leaving the water for the purpose of depositing eggs (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington, D.C., 578 pp.). We are aware of only two published records of aerial basking in *M. temminckii* (Ewert 1976. Herpetologica 32:150–156 and Shelby and Jensen 2002. Herpetol. Rev. 33:304); both involved juveniles and in the latter report basking was inferred but not actually witnessed.

On 5 May 2003 at ca. 1000 h in the Big Thicket National Preserve in eastern Texas, USA, a sub-adult *M. temminckii*, ca. 35–40 cm carapace length, was observed basking on a fallen tree above a creek. The turtle appeared to have been there for some time as its shell and the log were dry. At this point the creek was perhaps 8–10 m wide and 1.5–2 m deep with a moderately flowing current. The fallen tree trunk that the turtle was basking on was ca. 60 cm diameter with the uprooted end on the bank and the other end submerged in the creek. The tree trunk emerged from the water near the center of the creek at a 30–40° angle. To reach the basking spot, the turtle presumably climbed onto the submerged end of the tree and walked up the trunk 3–4 m to a spot 1 m above the surface of the water. It was positioned anterior end facing upward. We estimated air temperature at 24–29.5°C, with clear to partly cloudy skies. After watching the turtle for a period of 10–12 minutes, during which time it remained motionless, we approached for a closer view and an attempt to photograph the animal; at that point, the turtle dropped into the water, submerged, and disappeared from view.

A single *Graptemys* sp. was clearly observed basking on a nearby log simultaneously. Ewert (1976, *op. cit.*) also noted the proximity of "about seven" basking *Graptemys pseudogeographica sabinensis* and the similarity of chosen basking sites of the two species.

PODOCNEMIS EXPANSA (Amazonian Giant River Turtle). **PREDATION**. Grillotalpid crickets have been reported as turtle egg predators, specifically on *Dermochelys coriacea* in Guyana (Maros et al. 2003. Mar. Ecol. Prog. Ser. 249:289–296; Schouten et al. 1997. Stud. Nat. Hist. Carib. Region 73:63–69), and *Podocnemis expansa* in Colombia (Valenzuela 2001. J. Herpetol. 35:368–378). These reports note mole crickets as turtle egg predators but not as predators of hatchling turtles. Here we report on mole cricket predation on hatchling *P. expansa* in Venezuela.

In late March 2003, during the nesting season of *P. expansa* on Playita Island, middle Orinoco River, between Apure and Bolívar states, Venezuela, we found turtle nests with several dead hatchlings, as well as live hatchlings with injures to the head, neck, forelimbs, and hindlimbs. These injures were caused by two-clawed mole crickets, *Scapteriscus* sp. We noticed that nest infestation by mole crickets occurred near the end of the dry season and beginning of the rainy season (between March and May). Additionally, we observed that each infested nest contained a single cricket, typically an adult or in the last instar.

Although many nests were infested, the predation rates on hatchlings turtles were probably not significant. Hatchling predation in the nest by *Scapteriscus* sp. might be incidental to egg predation, which would explain the broken and damaged eggs in the nests late in incubation. Egg predation on *P. expansa* by *Scapteriscus* sp. crickets is here inferred, based on the published evidence (Maros et al., *op. cit.*; Schouten et al., *op. cit.*; Valenzuela, *op. cit.*) while the hatchling turtle predation is based on direct observation.

This note adds to the knowledge of the predators of *P. expansa* hatchlings and eggs, which is essential information for refinement of the conservation program for this endangered species.

The crickets were deposited at Museo de Biología de la Universidad del Zulia (MBLUZ-I-1123).

SIEBENROCKIELLA CRASSICOLLIS (Black Marsh Turtle). **FIRE SCARS**. Occurrence of fire scars on the shells of turtles is best described for the North American box turtle (*Terrapene carolina*) (Dodd et al. 1997. Herpetol. Nat. Hist. 5:66–72; Rose 1986. Southwest. Nat. 31:131–134; Smith 1958. Turtox News 36:234–237). Scars often result from the turtle being exposed to fire while partially buried in terrestrial habitats with the mid-dorsal and posterior areas of the carapace burned most frequently. *Siebenrockiella crassicollis* has been described as a bottom-walking aquatic turtle that inhabits deep ponds, marshes, sluggish streams, and swamps (Ernst and Barbour 1989. Turtles of the World. Smithsonian Inst. Press, Washington, D.C.; Iskandar 2000. Turtles and Crocodiles of Insular Southeast Asia and New Guinea. PALMedia Citra, Bandung, Indonesia; Liat and Das 1999. Turtles of Borneo and Peninsular Malaysia. Nat. Hist. Publ. [Borneo], Sabah, Malaysia). It is known to walk on land, presumably during movements between aquatic habitats (Liat and Das, *op. cit.*). We report here on observations of fire scars in a sample of *S. crassicollis* that suggests heretofore unrecognized terrestrial activity.

A large sample of *S. crassicollis* was among the 7500 turtles putatively from Malaysia that were confiscated by Hong Kong authorities on 11 December 2001. Approximately 3200 of the 16 species of turtles were shipped to the United States in January 2002 for processing and distribution to rescue centers, zoos, veterinarians, and university research programs (Hudson and Buhlmann 2002. Turtle and Tortoise Newslett. 6:11–14). A total of 1002 *S. crassicollis* was received in three shipments (Ades and Crow 2002. Turtle and Tortoise Newslett. 6:2–7). All had apparently been harvested aquatically, as some had fish hooks in their mouths or necks. During the triage, marking, and measuring process we discovered that several of these turtles were scarred on the carapace in various configurations with varying amounts of the keratin apparently removed by fire. A total of 45 *S. crassicollis* had such scars (4.49% of the total sample). Eighteen were males (129–202 mm carapace length) and 27 were females (137–199 mm CL); all were adults. In the data set available, two (both females) had scars on > 50% of the carapace, 13 (5 males, 8 females) had scars on 21–50% of the shell, and 19 (8 males, 11 females) had one or more smaller areas burned away. Fourteen turtles (6 males, 8 females) were burned on the dorsum of the carapace, 4 on the left side (2 each), 6 on the right side (3 each), and 14 on the rear of the carapace (5 males, 9 females). None of the fire scars was fresh and all were healed, indicating that each turtle survived its burns. Our interpretation of these scars as being derived from fire damage is consistent with those seen in other species such as *Terrapene carolina* (e.g., Dodd et al. 1997, *op. cit.*).

The existence of extensive fire scars on the carapaces of these bottom dwelling aquatic turtles (Ernst and Barbour, *op. cit.*) suggests that some individuals spent time buried terrestrially in habitats consisting of leaf litter or dead grass, possibly during times of the year when local residents set fires to grasslands and the grass understory in open forests; such fires are set annually (often in the spring) in parts of Asia to help generate fresh vegetative re-growth (KAB and JCM, pers. obs.). Our observations suggest that populations of *S. crassicollis* may inhabit seasonally-ponded wetlands with fluctuating hydrologies, but the reasons for a presumed terrestrial phase in the life history of *S. crassicollis* are not known. Investigation into this aspect of their behavior may reveal patterns of terrestrial habitat use heretofore unrecognized by chelonian biologists.

LACERTILIA

ACANTHOCERCUS ATRICOLLIS (Blue-headed Tree Agama). **ENDOPARASITES.** *Acanthocercus atricollis* is known from central and western Kenya, the southern half of Uganda, northern Rwanda and parts of Tanzania (Spawls et al. 2002. A Field Guide to the Reptiles of East Africa. Academic Press, San Diego. 543 pp.). To our knowledge, the only nematode species previously found in *A. atricollis* is *Strongyluris ornata* (Harwood 1935. J. Tennessee Acad. Sci. 19:132–141). The purpose of this note is to report two additional nematode species from *A. atricollis.*

Ten *A. atricollis* (4 females, 6 males) (mean SVL = 103 mm ± 14 SD, range = 69–123 mm) collected at Ntandi, (01°15'S, 29°59'E;1872 m) Uganda in June–July 1967 and deposited in the herpetology collection of the Natural History Museum of Los Angeles County (LACM 38748–38754, 38756–38758) were examined for helminths. The esophagus, stomach, small intestine, and large intestine were opened and separately examined for helminths under a dissecting microscope. The body cavity was also searched. Nematodes were placed in a drop of concentrated glycerol and allowed to clear for 24 h. They were then placed on a glass slide, cover-slipped and examined under a compound microscope. Found in the stomach were 42 *Abbreviata benoiti* (prevalence, infected lizards/lizards examined x 100 = 80%; mean intensity, mean number nematode per infected lizard = 5.3 ± 8.6 SD; range: 1–16). Found in the coelom were 7 *Saurositus agamae* (prevalence, 40%, mean intensity, 1.8 ± 1.0 SD; range: 1–3). The nematodes were deposited in the United States National Parasite Collection: *Abbreviata benoiti* (USNPC 94765) and *Saurositus agamae* (USNPC 94766).

Horchner and Weissenberg (1965. Zeit. Parasit. 25:491–500) described *Abbreviata benoiti* from *Acanthocercus cyanogaster* from the Congo. *Acanthocercus atricollis* is the second host reported to contain this nematode. *Saurositus agamae* has previously been reported from the agamids *Laudakia caucasica* (Sharpilo 1976. Izdat. "Naukova Dumka." Kiev, Russia. 287 pp.), *Agama agama* (Macfie 1924. Ann. Trop. Med. Parasit. 18:409–412), and *Agama mossambica* (Bain 1969. Ann. Parasit. Hum. Comp. 44:581–594). *Acanthocercus atricollis* represents a new host record for *Abbreviata benoiti* and *Saurositus agamae*; Uganda is a new locality record.

We thank Aaron Bauer (Villanova University) for confirming the identity of *Acanthocercus atricollis*.

BURSEY**, Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

AMPHISBAENA IBIJARA (NCN). **PREDATION**. Snakes, especially elapids, are important predators of amphisbaenians (Marques and Sazima 2004. *In* Marques and Duleba [eds.], Estação Ecológica Juréia-Itatins Ambiente Físico, Flora e Fauna, pp. 257–277, Ribeirão Preto, Holos Editora; Cunha and Nascimento 1993. Bol. Mus. Para. Emílio Goeldi, Sér. Zool., Belém, [9]:1–191). Here, we augment documentation of elapid predation on amphisbaenians with an observation of predation on the recently described *Amphisbaena ibijara* (Rodrigues et al. 2003. Phyllomedusa 2:22–26) by the fossorial *Micrurus ibiboboca* in NE Brazil.

At 2324 h on 9 March 2004, we collected an adult female *M. ibiboboca* (628 mm SVL) as it was resting on litter in an eucalyptus plantation near the municipality of Urbano Santos (3°12'28"S, 43°24'12"W; elev. 41 m), State of Maranhão, and placed it in a plastic bottle. The next morning, the snake regurgitated an adult male *A. ibijara* (198 mm SVL) with its anterior end partially digested and therefore was presumably ingested head first (Fig. 1).

Micrurus ibiboboca exhibits both diurnal and nocturnal activity, and is regionally common (Lima 2003. Composição e diversidade de serpentes em um mosaico de habitats no município de Urbano Santos, Maranhão. Dissertação de mestrado, Mus. Para. Emílio Goeldi, Belém-PA. 61 pp.). The frequency of *M. ibiboboca* predation on *A. ibijara* is not known, but might be common because both species appear to be common and use the same microhabitat. This represents the first record of an *A. ibijara* predator.

FIG. 1. *Amphisbaena ibijara* with the front end of body partially digested.

ANOLIS CAROLINENSIS (Green Anole). **BEHAVIOR.** Native to the southeastern United States (Smith 1946. Handbook of Lizards of the United States and Canada. Cornell Univ. Press. Ithaca, New York, 557 pp.), *A. carolinensis* was first reported in the wild in the Hawaiian archipelago on Oahu in 1950 (McKeown 1996. A Field Guide to Reptiles and Amphibians in the Hawaiian Islands. Diamond Head Publishing, Inc, Los Osos, California. 172 pp.). It has since spread to adjacent islands and was first documented from Kauai in 1987 (Mayer and Lazell 1992. Bull. Ecol. Soc. America 73:265). Based on observations in 1991 and 1994, Michael (1996. Elepaio 56:1–4) described a population of *A. carolinensis* and its persistence following a major hurricane. However, these visits provided only limited opportunity to draw parallels in behavior between this introduced population and populations of *A. carolinensis* in their native range. Moreover, data on introduced *A. carolinensis* populations are sparse. Hence, this report, which describes a follow-up visit made to the same site in 1998 earlier in the season than previous visits, afforded the opportunity to better describe similarities in *A. carolinensis* behavior to populations in its native range.

Between 26 June and 6 July 1998, I made observations of *A. carolinesis* living in landscape vegetation on the landward side of the Kuhio Shores condominium complex, located 3 km S of Koloa Town on the southern shore of Kauai. This is the same location studied in July–August 1991 and 1994; Michael (*op. cit.*) describes general aspects of this site. In 1992, Hurricane Iniki made landfall on southern Kauai and inflicted substantial damage to the condominium structure as well as the landscaping in which the *A. carolinesis* lived. Structural and landscape repairs were near completion during the 1994 visit. Landscape maintenance was less intensive in 1994 as compared to 1991 or 1998; watering was done every few days and little or no systematic raking or debris removal was apparent. Intensive landscape maintenance was not begun until reconstruction was completed so as not to interfere with repairs. By 1998, daily landscape maintenance such as watering, raking of debris, and pruning resumed to pre-Iniki levels.

In 1998, landscape plants consisted of a similar mixture of species of ornamental groundcover, shrubs, palms, and other trees as described in Michael (*op. cit.*). Multiple vegetation layers and an interconnected overstory of trees were the result of increased care (water, pruning, fertilizing). Groundcover plants were the same species but increased watering roughly doubled the height (to ca. 20 cm) of the stem-leaf matrix over that in 1994. The landscaped area was a roughly L-shaped unit ca. 3 m wide between the parking lot and condominium walkways; the short leg of this L was ca. 20 m and the long leg was ca. 50 m. In 1998, except for concrete walkways, groundcover occupied the entire landscaped area in a continuous bed, whereas in 1994, bare dry soil separated only a few isolated clumps of plants (ca. 3 x 3 m). In 1998, as in 1991, daily watering occurred. In 1998, three smaller palms replaced the single large palm tree near to which all *A. carolinesis* were observed in 1991 and 1994; each of the three palms was ca. 10 cm in diameter and 5–8 m tall.

Similar to previous years, I visual-encounter surveyed for *A. carolinesis* daily during daylight hours, usually mid-morning and mid-afternoon. Each lizard was classified as to gender (male, female, or unknown) and age group (adult, juvenile, or hatchling; *fide* Michael, *op. cit.*). Most animals were sexed using behavior and appearance, but not marked. Males were larger and had larger heads than females, displayed dewlaps and sagittal crests (no significant dewlap or sagittal crest in females) and engaged in fights with other *A. carolinesis* (rare in females). I also made random observations of *A. carolinesis* at four additional localities (Koloa Town, Lihue, Kapaa, and Kilauea) around Kauai. While less systematic than observations made at Kuhio Shores, they offered a point of reference for study of the Kuhio Shores population.

I recorded an average of 2.6 *A. carolinesis*/day (s = 1.7, range: 1–6, N = 8 days) in 1998, a mean of 2.7 *A. carolinesis*/day (s = 1.6, range: 1–6, N = 11 days) in 1991, and a mean of 2.3 *A. carolinesis*/day (s = 2.3, range: 1–4, N = 11 days) in 1994. No significant differences were found in the numbers of *A. carolinesis* encountered among years (Kruskal-Wallis test: df = 2, $P = 0.8928$). However, I observed only adult green *A. carolinesis* at Kuhio Shores in 1998, whereas in 1991 and 1994, 87% (N = 26) and 84% (N = 21) of the *A. carolinesis* I found were non-adults. Numbers of adults and non-adults in 1991 were not significantly different from adult and non-adult numbers in 1994 (Fisher's Exact Test: $P > 0.9999$), but adult and non-adult numbers in 1998 were significantly different from those in each of 1991 and 1994 (Fisher's Exact Test: $P < 0.0001$; adjusted a for three tests was 0.17). Observations of *A. carolinensis* made around the island during each year visit paralleled those made at Kuhio Shores, i.e., most *A. carolinesis* seen during the 1991 and 1994 visits were non-adults, whereas only adults were seen in 1998. In 1998, it also appeared that adults responded to the observer by displaying, and thus, drew attention to themselves. In 1991 and 1994, the few adults observed did not initially respond to the observer; they remained still or fled but did not bob or display dewlaps or sagittal crests.

Anolis carolinensis numbers were similar among years, but the salient aspect of observations was finding exclusively adults, especially behaviorally prominent males, in 1998. As similar observations were made throughout Kauai in 1998, the age group pattern of observations was not localized. This difference might reflect typical behavior for these age groups through a seasonal breeding cycle. In its native range, *A. carolinesis* breed from early May to late July (Jenssen and Nunez 1998. Behaviour 135:981–1003). The 1991 and 1994 visits were in late July–early August, whereas the 1998 visit occurred in late June–early July. Greater visibility, particularly of males in 1998, differed from the two previous visits. This pattern would fit observations of free-ranging *A. carolinesis* in their native range, where males spent most of their time near the ground and displayed more than 15 times as often during May–July versus August–September (Jenssen et al. 1995. Herpetol. Monogr. 9:41–62). This behavior changed significantly at the July/August boundary, when males switched from being socially oriented to being largely solitary animals (Jenssen et al., *op. cit.*).

Lack of juveniles during the 1998 observations has at least two likely explanations. The first is that eggs had not yet hatched. In Florida, egg-laying occurs during May–July with hatching occurring as early as mid-June (Smith 1946, *op. cit.*). The 1998 visit might have occurred just before hatching. The second possibility is that hatchlings were less detectable in the lusher vegetation present in 1998. In 1991 and 1994, the hatchlings were observed on the surface of groundcover; juvenile behavior would also had to have changed in 1998 for them to remain undetected. Focused observations over at least the June–August interval would be necessary to clarify the basis of this pattern.

CHAMAELEO MONTIUM (Mountain Chameleon). **REPRODUCTION.** *Chamaeleo montium* inhabits submontane to montane forests, secondary forests, and farm bush at 550–1200 m elevation in SW Cameroon (Hofer et al. 2003. J. Herpetol. 37:203–207). The species has a light green ground color in both resting or unexcited states (Neças 1995. Chamäleons. Bunte Juwelen der Natur. Edition Chimaira, Frankfurt. 249 pp.). Maturity occurs in the first year, gestation in two months (Neças, *op. cit.*) and reproduction appears to be aseasonal (pers. obs). Detailed field studies of this species are lacking. Hence, we describe aspects of *C. montium* reproductive behavior, including mate attendance, copulation, rejection, and coloration in SW Cameroon.

The study site, a cultivated garden adjacent to secondary forest and farmbush, was in the village of Nyasoso (4°49'289"N, 9°40'826"E; elev. 850 m) at Mt. Kupe, South West Province. The study period, 10 November 2002 to 29 March 2003, encompassed all of the dry season and the beginning of the rainy season. We observed an adult female (75 mm SVL) with missing tail tip which facilitated identification. We conducted observations on this female opportunistically, with multiple observations occurring on several days, especially when a male was nearby. We viewed chameleons from a 2-m distance, which did not appear to disturb their behavior. On 10 November, we observed a male (No. 1) with the female. Both chameleons were found at a height of ca 1.8 m in a *Penianthus* (shrub)/guava tree (*Psidium*) growth. The male was following the female, which walked very slowly away. When walking ceased, the female continued movement with a slow rocking motion; the female was dark brown to black in color with yellow spots on the head. The male was light green with bright yellow lateral stripes, head crowned with turquoise; small white spots were sprinkled throughout the head and body, and his throat was inflated.

The male mounted the female for copulation, pressing his chin flat against the female's body, head coloration remaining brilliant while the stripes and spots faded. The female remained dark, pressed her body flat against the branch and lifted the base of her tail slightly. The male's tail moved under the female's as he attempted to press his cloaca against hers. Duration of this courtship and copulation sequence was ca. 20 min. This male exhibited postcopulatory mate guarding, that is, he remained next to but not in contact with the female, throughout this and the following day. The female's color returned to green the following day. We marked the male with a small dot of brown paint on the flank before his departure; this mark did not appear to affect any behaviors involving himself and other chameleons.

On 2 December, we again observed this female exhibiting a

dark brown color and found a second male chameleon (No. 2) ca. 20 cm away. On 3 and 4 December, the color of the female had returned to green with bright yellow spots over the rump; Neças (*op. cit.*) indicates that this color pattern represents a rejection coloration for this species. Number 2 was resting ca. 10 cm away and was dark with turquoise spots around the crown of its head. Positioning of the two chameleons varied from head to tail—male posteriorly—or tail to tail. We similarly gave this male a unique paint mark. On 5 December, the female exhibited black coloration and aggressively chased male No. 2 away. Her dark coloration remained throughout the following day. This sequence characterizes a mating rejection (Cuadrado 2000. Ethology 106:79–91).

The female was found to be gravid (verified by abdominal palpation) on 5 January. This female was observed 74 times in the 56-day period, and no other males were seen in the vicinity of the female, so the eggs might be the result of the previously described presumably successful mating observed with male No. 1. On 17 January, the female was observed perched close to the ground; she was palpated, but lacked calcified eggs; egg deposition is thought to have occurred on that date (68 days post- mating).

On 23 January, male No. 1 was again found tending this female. Mating was observed at 1600 h on the following day, with a similar pattern and duration as previously described. This male was again with the female for two days, departing on 26 January. Abdominal palpation revealed the presence of eggs on 5 March. Based on behavior and abdominal palpation, the female is thought to have laid eggs on 25 March, 61 days post mating.

Notably, male No. 1 appeared twice precisely when the female was receptive and was not detected nearby when she was not. This same male was observed interacting with an unknown female at a second location mid-January, so might have been engaged in reproductive pursuits throughout our study period. Whether male *C. montium* are attuned to the temporal patterns of females which exhibit repeated reproduction is unknown.

CNEMIDOPHORUS COSTATUS BARRANCARUM (Barranca Whiptail Lizard) **REPRODUCTION**. We augment preliminary findings on reproduction for *Cnemidophorus costatus barrancarum* (= *Aspidoscelis costata barrancarum*; Reeder et al. 2002. Amer. Mus. Novitat. 3365:1–61) presented in Walker et al. (2003. Herpetol. Rev. 34:365). We dissected 60 specimens in the Herpetological Collection of Unidad de Biología, Tecnología y Prototipos (UBIPRO) collected by JLE at the periphery of the range of the subspecies in southwestern Chihuahua, México, in 2002 (9015–9018, 9053, 9071–9073, 9240–9243, 9280, 9287, 9331, 9347, 9354, 9355, 9365, 9374, 9420, 9471, 10599, 10600, 10625, 10626. 10633, 10651, 10652) and 2003 (11334–11336, 11365, 11366, 11392–11396, 11475–11482, 11503–11506, 11508–11510, 11528–11533) in addition to the 14 collected by him in 2000 (5908–5910, 55918, 5940) and 2001 (7316–7319, 7328–7330, 7369, 7373) and previously discussed by Walker et al. (2003, *op cit.*). Data are presented by sex as ratios, ranges of variation, and/or means (to one digit after the decimal) ± 1 SE. Numbers of males and females of *C. c. barrancarum*, respectively (in parens), by year were: 2000 (1:4); 2001 (2:7); 2002 (16:13); 2003 (22:9). Numbers of males and females, respectively (in parens), by size (as 10 mm SVL increments) in the UBIPRO sample were: 40–49 mm (0:2); 50–59 (4:1); 60–69 (2:6); 70–79 (7:10); 80–89 (10:10); 90–99 (9:4); and 100–112 (9:0). Data for the 2002 and 2003 samples, added to information in Zweifel (1959. Bull. Amer. Mus. Nat. Hist. 112:57–116) and Walker et al. (2003, *op. cit.*), update knowledge of reproductive characteristics for *C. c. barrancarum* as follows: clutch size, 4.3 ± 0.33 (range 2–8, N = 24) eggs; mean size of adult females, 81.3 ± 1.65 (range 67–97, N = 27) mm SVL; mean size of adult males, 88.9 ± 1.96 (range 69–112, N = 36) mm SVL. One female (UBIPRO 11478 of 97 mm SVL) contained only two left and no right yolked ovarian follicles; implying reproductive senescense if large size reflects old age. Another female (UBIPRO 11532 of 88 mm SVL) had a clutch arrangement not seen among hundreds of *Cnemidophorus* lizards JMW has previously dissected. Besides the presence of 4 left and 3 right yolked ovarian follicles of 8.0–9.5 mm in diameter, the left oviduct of this individual contained an unusually large egg of 8.0 x 19.0 mm. Females of *Cnemidophorus* with oviductal eggs typically have either no yolked ovarian follicles (usual case) or very small ones of 3–4 mm in diameter. Clutch size was positively correlated with SVL (adjusted r^2 = 0.47, N = 24) and removal of the outlier UBIPRO 11478 markedly strengthened the relationship (adjusted r^2 = 0.70).

SMITH**, EBIO, and Museum, University of Colorado, Boulder, Colorado 80309–0334, USA (e-mail: hsmith@colorado.edu).

CNEMIDOPHORUS NEOMEXICANUS (New Mexico Whiptail Lizard). **REPRODUCTION**. Studies of reproductive characteristics in parthenogenetic *Cnemidophorus neomexicanus* (= *Aspidoscelis neomexicana*; Reeder et al. 2002. Amer. Mus. Novitat. 3365:1–61) in New Mexico (Medica 1967. Bull. South. California Acad. Sci. 66:251–276; Christiansen 1971. Amer. Mus. Novitat. 2442:1–48) have revealed few reproductively active females in July and none in August samples. In the most detailed study (Christiansen 1971, *op. cit.*), gravid females were collected as early as 27 April and as late as 19 July; however, only 12/75 (16%) females in July samples were gravid.

We used University of Arkansas Department of Zoology (UADZ) specimens collected by JEC in southwestern New Mexico to add significant details to knowledge of reproduction in *C. neomexicanus*. Eight adults of this species collected on 6 (UADZ 6180–6183, 6195, 6196 from 21.3 km NW of jct New Mexico Hwy 90 and US Hwy 70 on 70 W) and 7 (UADZ 6188, 6189 from 12.2 km NW of jct New Mexico Hwy 90 and US Hwy 70 on 70

W) August 1998 in Hidalgo County included two gravid females: UADZ 6188 (69 mm SVL, 10.2 g) and UADZ 6189 (70 mm SVL, 10.0 g). Each had two eggs of ca. 9 x 15 mm, one in each oviduct. Nine adults collected on 10 (UADZ 7070–7074) and 12 (UADZ 7093–7096) August 2002 2.9 km N of the Grant County boundary on New Mexico Hwy. 464, included a gravid female UADZ 7074 (68 mm SVL, 10.2 g) with one egg in each oviduct of ca. 9 x 15 mm. These observations based on August collections extended the known reproductive cycle of *C. neomexicanus* by almost a month by a similar percentage of reproductive females (3/17, 17.6%) as was reported among July females from Bernalillo County by Christiansen et al. 1971 (*op. cit.*). Moreover, based on reports of incubation periods of 46 (Christiansen 1971, *op. cit.*) to 54 (Medica 1967, *op. cit.*) days in *C. neomexicanus*, the gravid individuals identified in this note extend potential egg hatching dates in this species from between 19 July and 16 August (Christiansen 1971, *op. cit.*) to as late as October. Such late-season neonates would have a feeding and growth period of about a month before the onset of suboptimal fall temperatures in Hidalgo and Grant Counties, New Mexico. Variable hatching dates over more than two months might account for the wide range of SVLs observed among second-year individuals of *C. neomexicanus* in some April–June collections from southwestern New Mexico. Yearly temperature conditions and amount and timing of rainfall likely strongly influence the reproductive cycle in this species.

Specimens of whiptail lizards were collected in New Mexico under authority of permits granted to the authors by the New Mexico Department of Game and Fish.

CNEMIDOPHORUS SEXLINEATUS (Six-Lined Racerunner). **BEHAVIOR**. Among diverse thermoregulatory behaviors that vertebrates perform, alternate foot-lifting behavior has been documented in the South African Namib Desert lacertid, *Aporosaura anchietae* (Louw and Holm 1972. Madoqua 1:67–85). Characterized by brief synchronous lifting of trans-leg pairs, this behavior is performed to avoid prolonged contact with hot substrates. Here, we report similar behavior in the Six-Lined Racerunner, *Cnemidophorus sexlineatus,* from central Florida.

We made these observations while conducting research on the Florida Sand Skink (*Neoseps reynoldsi*) in July 1994 on a rosemary scrub habitat in Orange County near Orlando (24°21'31"N, 81°35'28"W; elev. 30 m). Scrub habitat is characterized by low stature oak canopies, with a midstory of palmetto and other woody plants, and herbaceous and lichen ground cover. During the summer, sand surface temperatures can reach 44.4°C (Collazos 1998. Microhabitat Selection in *Neoseps reynoldsi*, the Florida Sand-swimming Skink. MSc Thesis, University of South Florida. 81 pp.). We cornered an adult (ca. 100 mm SVL) *C. sexlineatus* at the base of a thick-trunked (ca. 14 cm diam) Myrtle Oak (*Quercus myrtifolia*). During a 15-sec observation period, this individual performed at least four bouts of alternate foot-lifting behavior before it disappeared into a nearby Saw Palmetto (*Serenoa repens*) thicket.

We are unaware of any reference to alternate foot-lifting behavior in association with agonistic interactions in any animal taxa. Given the high surface temperatures (air temperature ranged from 33.3 to 37.2°C based on local weather data), we believe that this behavior was a thermoregulatory response rather than anti-predator behavior directed at us as observers. The context of further observations will be needed to verify our interpretation of this behavior. Alternate foot-lifting behavior has been anecdotally observed in few lizards other than *A. anchietae* (i.e., *Cnemidophorus lemniscatus*, Laurie Vitt, pers. comm.), but has seldom if ever been published. If our interpretation is correct, this would represent the first time that alternate foot-lifting behavior, putatively thermoregulatory, has been reported in *C. sexlineatus*.

Submitted by **PABLO R. DELIS**, Biology Department, Shippensburg University, 1871 Old Main Drive, Shippensburg, Pennsylvania 17257, USA (e-mail: prdelis@wharf.ship.edu); and **ERIC P. SUTTON**, Sarasota County Natural Resources, 2817 Cattlemen Road, Sarasota, Florida 34232, USA.

CNEMIDOPHORUS SEXLINEATUS VIRIDIS (Prairie Racerunner). **MAXIMUM BODY SIZE**. Recently, the maximum total length of *Cnemidophorus sexlineatus viridis* (= *Aspidoscelis sexlineata viridis*) was reported as 267 mm (84 mm SVL; Toal and Collins 2003. Herpetol. Rev. 34:59) as determined from an adult female from the southern Ozarks of Missouri (Barry County). Herein, I report on a new maximum body size for this species from Arkansas.

On 28 December 1974, I unearthed an adult female *C. sexlineatus viridis* from a hibernation burrow on a roadside embankment, 5.1 km N Dover off State Hwy 7 (Pope County; 35°27.98'N, 93°8.25'W; elev. 218 m). This female was 90 mm SVL at the time of collection and had a 115 mm partly regenerated tail (regenerated portion = 77 mm). Re-measurement of the female on 28 February 2004 yielded the original SVL, which exceeds the previously reported maximum by 6 mm.

The specimen was deposited in the Arkansas State University Museum of Zoology herpetological collection (ASUMZ 28204) and collected under the authority of an Arkansas Game & Fish Commission scientific collection permit.

Submitted by **STANLEY E. TRAUTH**, Department of Biological Sciences, Arkansas State University, State University, Arkansas 72467, USA; e-mail: strauth@astate.edu.

COLEODACTYLUS MERIDIONALIS (NCN). **PREDATION**. *Coleodactylus meridionalis* is a poorly known litter-dwelling gekkonid lizard distributed in the Caatinga and Atlantic Rainforest of northeastern Brazil (Vanzolini et al. 1980. Répteis das Caatingas, Academia Bras. Ciências, São Paulo. 161 pp.). Recently, Dias et al. (2003. Herpetol. Rev. 34:142–143) provided data on diet and feeding habits for *C. meridionalis* from "restinga" (an herb and shrub association on sand dunes along the Brazilian coastline), a habitat within the Brazilian Atlantic rainforest biome. Here, we report a predation event on an individual of *C. meridionalis* by a

sympatric tropidurid lizard, *Tropidurus hygomi*, from a restinga site in northeastern Brazil.

During analysis of the stomach contents of 24 *T. hygomi* from Dunas do Abaeté (12°57'03"S, 38°22'30"W; elev. 15 m), municipality of Salvador (Bahia State), one of us (MMFV) found remnants of a *C. meridionalis* in the stomach of an adult female *T. hygomi* (46.2 mm SVL). Comparison with vouchers of *C. meridionalis* from the Museu de Zoologia da Universidade Federal da Bahia (MZ-UFBA) confirmed the identity of the prey. The female *T. hygomi* was deposited at the MZ-UFBA (UFBA-LAG 639).

Tropidurus hygomi is a diurnal, heliothermic, terrestrial tropidurid endemic to "restinga" habitats of northeastern Brazil (Vanzolini and Gomes 1979. Papéis Avulso de Zoologia [São Paulo] 21:243–259). This species, typically a sit-and-wait predator, displays opportunistic feeding behavior on invertebrates and small vertebrates, including other lizards (Vargens 2003. Ecologia de *Tropidurus hygomi* [Sauria: Tropiduridae] na restinga do Abaeté – Salvador –Bahia. Bachelor's Thesis, Departamento de Zoologia, Univ. Fed. da Bahia, 45 pp.). At Dunas do Abaeté, *T. hygomi* uses mostly habitats covered with leaf litter, the microhabitat where *C. meridionalis* is typically found, thereby facilitating encounters. Small litter-dwelling lizards like *C. meridionalis* are rarely surface visible, so opportunistic foraging might best explain their predation by sympatric tropidurids, including *T. torquatus* (Araújo 1991. Rev. Brasil. Biol. 51:857–867; Teixeira and Giovanelli 1999. Rev. Brasil. Biol. 59:11–18), *T. hispidus* (Vitt and Carvalho 1995. Copeia 1995:305–329; Vitt 1995. Occ. Pap. Oklahoma Mus. Nat. Hist. 1:1–29), and *T. semitaeniatus* (Vitt, *op.cit.*).

Carlos Frederico D. Rocha and Rejâne Maria Lira-da-Silva kindly reviewed the manuscript. The Conselho Nacional do Desenvolvimento Científico e Tecnológico (CNPq) and Fundação de Amparo à Pesquisa do Estado do Rio de Janeiro (FAPERJ) provided funding.

Submitted by **MARTA MONIZ FREIRE VARGENS** (e-mail: mvargens@yahoo.com.br), **ANNELISE BATISTA D'ANGIOLELLA,** Departamento de Zoologia, Instituto de Biologia, Universidade Federal da Bahia, Campus de Ondina, Salvador, BA; and **EDUARDO JOSÉ DOS REIS DIAS** (e-mail: ejrdias1@bol.com.br), Setor de Ecologia, Instituto de Biologia Roberto Alcântara Gomes, Universidade do Estado do Rio de Janeiro, Rua São Francisco Xavier 524, Maracanã, 20550-019, Rio de Janeiro, RJ, Brazil.

COPHOSAURUS TEXANUS (Greater Earless Lizard). **SAUROPHAGY.** *Cophosaurus texanus*, a generalist invertebrate consumer, is known to prey on members of at least 12 different arthropod orders (Maury 1995. J. Herpetol. 29:266–272). Its diet is well known, but neither saurophagy nor cannibalism has been reported. Here, we provide observations of cannibalism and saurophagy for *C. texanus* from Nuevo Leon, México.

At 1246 h on 28 September 2002 in Casa Blanca Canyon near the municipality of Santa Catarina (25°38'13.7"N, 100°42'39.1"W; elev. 1360 m), we observed a female *C. texanus* (48 mm SVL, 59 mm tail) capture and eat a small conspecific male (25 mm SVL). Local habitat is desert scrub and chaparral on a calcareous geology. The female *C. texanus*, which was perched on a rock of ca. 30 cm high, ran a 0.5 m distance to capture the young male that was perched on a smaller rock. The male, captured by one side of the head (after dissection, a semi-circular depression was observed in the parietal region), was swallowed with slow undulatory movements; ingestion took about 3 min. The ingested lizard's tail was in three parts (total length ca. 25 mm). The female (UANL 6341) was collected, dissected, and deposited in the herpetological collection of the Universidad Autónoma de Nuevo León. Dissection of the stomach also revealed the forelimb and the hindlimb of a *Sceloporus couchii,* presumably from the same individual. Based on comparison of the limb fragments with preserved specimens, the ingested *S. couchii* was ca. 26 mm SVL.

Our observations show that *C. texanus* can prey on small lizards, including conspecifics. We thank Marc P. Hayes and Glafiro Alaniz F. for their help with this note.

CROCODILURUS AMAZONICUS (Jacarerana). **DIET.** *Crocodilurus amazonicus* is a semi-aquatic macroteiid (males 80–248 mm SVL; females 83–320 mm SVL) widely distributed in the Amazon Basin (Ávila-Pires 1995. Zool. Verh. Leiden 299:1–706). Little is known of its ecology; beyond general information on its semi-aquatic habit, one report on its diet exists (Márcio Martins in Avila-Pires, *op. cit.*) noting that 10 young *Bufo marinus*, a large odonate, and one hemipteran were found in the stomach of an adult. Here, we add to the sparse dietary data with the first record of a reptile in *C. amazonicus* diet.

During a field survey for the project "Herpetofauna das savanas amazônicas: subsídios para sua preservação" in August 2003 in the city of Humaitá, State of Amazonas, Brazil (7°30'22"S, 63°01'15"W; elev. 60 m), we collected a series of 30 *C. amazonicus* on the margin of the Puruzinho River. In examination of the stomach contents of an adult (200 mm SVL) female, we found an intact young male *Helicops polylepis* (Colubridae: Xenodontinae) with a total length of 310 mm.

Helicops polylepis is a semi-aquatic, nocturnal snake that is also widely distributed in Amazonia (Cunha and Nascimento 1978. Publ. Avul. Mus. Par. Emílio Goeldi 31:1–218; da Silva and Sites 1995. Conserv. Biol. 9:873–901). As *Crocodilurus* spends most of the time in water or near water, frequent opportunity to encounter *H. polylepis* might exist.

The lizard was deposited in the Coleção Herpetológica da Universidade de Brasília, (CHUNB 32594). We thank Adrian Garda and Alexandra Bezerra for field assistance. The "Fundação O Boticário de Proteção a Natureza" provided financial support to D. O. Mesquita.

CTENOPHORUS FIONNI (Peninsula Dragon Lizard). **CANNIBALISM**. Cannibalism has been reported in many reptiles (Mitchell 1986. Cannibalism in Reptiles: A Worldwide Review. SSAR, Oxford, Ohio. 37 pp.), but has rarely been recorded among Australian agamids. One such agamid, *Ctenophorus fionni*, is restricted to rocky habitats on the Eyre Peninsula in South Australia. Little is known of this medium-sized lizard (96 mm max. SVL), which seems to be largely insectivorous (Johnston 1997. Behavioural Ecology of the Peninsula Dragon lizard *Ctenophorus fionni*. Ph.D. dissertation. Flinders University, Adelaide, 307 pp.). Here, I report the first record of cannibalism for this species.

During a mark-recapture study of *C. fionni* on 2 February 1992, I caught an adult male (71.5 mm SVL, 14.0 g) at Secret Rocks (33°12'S, 135°51'E; elev. 279 m), South Australia. While processing this lizard, I found a second, recently killed individual of the same species in his gullet. The dead lizard was subsequently regurgitated (Fig. 1). The size of the regurgitated lizard (32 mm SVL) and the timing of the observation indicate that it was a hatchling (Johnston 1999 J. Herpetol. 33:694–698). After being photographed, the adult male was released and the dead juvenile was discarded.

The South Australian National Parks & Wildlife Service, and the Flinders University Animal Ethics Committee granted permits for this work.

FIG. 1. Male *Ctenophorus fionni* regurgitating a conspecific juvenile, Secret Rocks, South Australia, 2 February 1992.

CYCLURA CYCHLURA INORNATA (Allen Cays Iguana). **MORTALITY**. Mortality in adult *Cyclura cychlura* is rarely reported. Apart from recent records of predation on *Cyclura c. cychlura* on Andros Island in the Bahamas (Knapp 2004. Caribbean J. Sci. 40:265–269), no observations of natural mortality are recorded for this species (e.g., see Coenen 1995. Bahamas J. Sci. 2:8–14). Hence, we report a distinctive instance of mortality from the Allen Cays, northern Exuma Islands, Bahamas.

During mid-afternoon 12 May 2004, we discovered a female Allen Cay Iguana (27.0 cm SVL, 35.5 cm tail, 530 g) trapped between the multiple trunks of a tree (cf. *Drypetes diversifolia* fide Sandra Buckner) on Leaf Cay, an island in the Allen Cays (Fig. 1; see Iverson et al. 2004. Herpetol. Monogr. 18:1–36 for map and aerial photograph). This female was originally toe-clipped and PIT-tagged on 11 March 1998 at a SVL of 26.2 cm and an estimated age of 12.5 years; she had been recaptured during field work in 2001, 2002, and 2003 (weighing 705 g at the last capture). She was lethargic and somewhat emaciated when removed from between the branches, weighing 148 g less than estimated based on a regression equation relating SVL to mass for 168 other females captured on Leaf Cay during the same trip. She was still very sluggish when released 48 h later, following attempts to rehydrate her and nourish her with force-fed bananas. Although this iguana was still alive when discovered, we had previously found three mummified carcasses or nearly intact skeletons of subadult or small adult Allen Cay iguanas wedged between tree trunks on Leaf Cay in June 2001, and one on nearby U Cay (= Southwest Allen Cay) in May 2002. We also observed a mummified carcass of an adult *Cyclura rileyi* on Bush Hill Cay in the Exuma Land and Sea Park, central Bahamas on 21 May 2003 that had been similarly trapped in the crotch of a tree.

No predators capable of wedging an iguana between tree trunks occur on these islands. However, arboreality is common in the genus *Cyclura* (Iverson 1979. Bull. Florida St. Mus. Biol. Sci. 24:175–358), and the observed mortality likely occurred as individuals descended from trees where they had been feeding and/or thermoregulating. Many West Indian trees have multiple trunks and smooth bark; we suspect that the often poorly controlled descent (i.e., sliding) of these iguanas down tree trunks creates enough momentum to sometimes pin them between tree trunks such that they are unable to extricate themselves. This would explain why we have never observed the phenomenon in young iguanas or smaller cohabiting lizard species despite over 18,000 person-hours of field work over 25 years. The lack of similar observations for large adult *C. cychlura* may be a function of their reduced arboreality. This form of accidental death might occur with some frequency among subadult or small adult West Indian rock iguanas. We are unaware of similar records of mortality for any other lizard.

CYCLURA LEWISI (Grand Cayman Blue Iguana). **HATCHLINGS.** Little is known of the behavior and ecology of hatchling *Cyclura* (Sauria: Iguanidae) and nothing is known about this age group in endangered *Cyclura lewisi*. Hence, we provide preliminary data on *C. lewisi* hatchling behavior and sizes.

On 26 August 2001, we measured and observed wild *C. lewisi* hatchlings from two nests that had been enclosed prior to emergence at the Queen Elizabeth II Botanic Park, Grand Cayman (19°19'N, 81°10'W; elev. 2 m). Hatchlings were measured after emergence, then allowed to recover for 5–10 min. Subsequently, one wall of the enclosure was removed, and hatchlings were allowed to exit at their own pace to minimize altering their behavior. We then followed five of them for focal animal observations, but lost sight of all of them in < 1 h.

All iguanas tongue-touched the ground as they moved away from the nest site. One hatchling headbobbed several times (2–4 bobs per episode) as it moved away, but we did not see the other iguanas display in this way. Three of five hatchlings climbed into trees within 20 min of leaving the nest enclosure, suggesting that hatchling *C. lewisi* might be more arboreal than adult conspecifics. Within 10 min of release, we witnessed an attempted predation on one hatchling by a snake, the Grand Cayman Racer (*Alsophis cantherigerus caymanus*). The iguana, apparently reacting instinctively to the snake's strike movement, escaped by jumping away and running ca. 3 m while the snake retreated back into a low wall, probably disturbed by the observer's presence. We had previously witnessed snakes trying to gain access to hatchling *C. lewisi* in enclosures, but this was the first direct observation of attempted snake predation on *C. lewisi* hatchlings in the wild.

One hatchling returned to the nest chamber on the same day after leaving the nest site and enclosure. The iguana might have been going to use the nest as a nocturnal retreat, but we accidentally disturbed it during nest excavation that evening.

Two of five hatchlings tested a potential food item within 10 min of leaving the nest enclosure, but each rejected the item (a dried piece of grass and a logwood leaf, *Haematoxylum campechianum*). Less than 15 min after leaving the enclosure, one hatchling spent 35 sec drinking rainwater from the edge of a pond. Another hatchling purposefully ate soil, a behavior we have also seen in adults.

Wild hatchlings had absorbed most of their yolk sac by the time they emerged, had closed umbilicae, were dry, and seemed markedly thinner than conspecifics immediately after the latter hatched from eggs incubated under controlled conditions. Captive hatchlings were wet at hatching, had abdomens swollen with yolk and visibly unsealed umbilicae, and showed no interest in food or water until 2–3 weeks after hatching. The difference in yolk supply between captive-hatched and wild-emerged iguanas, coupled with the immediate drinking and foraging behavior displayed by the latter, implies a post-hatching underground residence time in the wild. Hatchlings of other species of iguanas (subfamily Iguaninae) have been suggested to remain in the nest chamber for several days to two weeks before emergence (Wiewandt 1977. Ph.D. dissertation. Cornell University, Ithaca, New York; Christian and Tracy 1982. *In* Burghardt and Rand [eds.], Iguanas of the World: Behavior, Ecology, and Conservation, pp. 366–379. Noyes, Park Ridge, New Jersey).

Wild hatchlings averaged 94.3 mm SVL ($s = 7.4$ mm, $N = 6$), and were significantly smaller than captive-bred hatchlings (mean SVL = 100.8 mm, $s = 3.6$ mm, $N = 17$; Student's t test, $t = 2.865$, $P = 0.009$). The difference in size between wild and captive hatchlings might reflect differences in moisture levels or temperatures during incubation or differences in egg size relating to the age or nutritional state of the mothers (Packard and Packard 1988. *In* C. Gans and R. B. Huey [eds.], Biology of the Reptilia, vol.16, pp. 523–605. Alan R. Liss, New York).

Our observations were collected during research approved by the National Trust for the Cayman Islands and the Queen Elizabeth II Botanic Park.

Submitted by **RACHEL M. GOODMAN**, 569 Dabney Hall, Department of Ecology and Evolutionary Biology, University of Tennessee, Knoxville, Tennessee 37996, USA (e-mail: rmgoodman@utk.edu); and **FREDERIC J. BURTON**, Blue Iguana Recovery Programme, P.O. Box 10308 APO, Grand Cayman, Cayman Islands.

ENYALIOIDES COFANORUM (Cofan Wood Lizard). **REPRODUCTION**. *Enyalioides cofanorum* is a terrestrial hoplocercid known from the Amazonian lowlands of Ecuador and Peru. A female collected from Santa Cecilia, Ecuador in March 1972 had two ovarian eggs (ca. 26 mm long) and another collected in July contained two oviductal eggs (ca. 28 mm long) (Duellman. 1978. Misc. Publ. Mus. Nat. Hist. Univ. Kansas 65:1–352). Five adult females collected at Santa Cecilia averaged 104 mm snout–vent length (SVL; range: 91–115 mm; Duellman 1973. Herpetologica 29:228–231). Here, I augment the limited data on this species with observations made in eastern Amazonian Ecuador.

On 31 July 2001, a female *E. cofanorum* was collected resting horizontally on a branch 0.5 m above ground in primary terra firme forest at the Tiputini Biodiversity Station (0°37'05"S, 76°10'19"W; elev. 215 m). This field station, managed by the Universidad San Francisco de Quito, is located 280 km ESE of Quito on the north bank of the Tiputini River next to Yasuni National Park, Orellana Province, Ecuador (Cisneros-Heredia 2003. *In* De la Torre and Reck. [eds.], Ecología y Ambiente en el Ecuador: Mem. I Congr. Ecología y Ambiente, Ecuador País Megadiverso. CD. Universidad San Francisco de Quito, Ecuador). The lizard was gravid and dissection revealed five shelled eggs. Eggs had a mean length of 25.6 mm (24.9–26.0 mm), a mean width of 10.4 mm (10.0–11.3 mm), a mean mass of 1.8 g (1.7–1.9 g; total clutch mass = 9.1 g), and a mean volume of 1.5 cm^3 (1.4–1.7 cm^3). The lizard was 95.7 mm SVL, 120.8 mm tail length, and mass (without eggs) of 27.9 g. The female and eggs (DFCH-USFQ 0558) were deposited at the Universidad San Francisco de Quito.

Based on these data, clutch size in *E. cofanorum* ranges from 2 to 5. This range is smaller, but overlaps that of *E. laticeps*, a sympatric arboreal/terrestrial congener with larger clutches (5–7 eggs, mean = 6.2), smaller eggs (15.0–16.6 mm, mean = 15.6 mm) and larger females (107–125 mm SVL, mean SVL = 114 mm; Duellman 1978, *op. cit.*; Vitt and De la Torre 1996. Research Guide Lizards of Cuyabeno. Mus. Zool. QCAZ-PUCE Monogr. 1:1–165).

I am grateful to Andres Leon, Leo Zurita, and Susana Cardenas for field companionship and assistance, and to Kelly Swing, Marc Hayes, and Maria Elena Heredia for critically reading the manuscript. I also thank Maria Elena Heredia and Laura Heredia

for financial and moral support. Tiputini Biodiversity Station-Universidad San Francisco de Quito provided institutional, logistic, and financial support. The Ministry of Environment of Ecuador provided the scientific research authorization Nº 19-IC-FAU-DFN. This is publication No. 3 of the project "Study of the Herpetofauna of the Tiputini Biodiversity Station" and contribution No. 2 of the Laboratorio de Anfibios & Reptiles, Universidad San Francisco de Quito.

EUMECES FASCIATUS (Five-lined Skink). **PREDATION**. Terrestrial predators pose a risk to many lizards; however, aquatic predators might also threaten terrestrial lizards that use the edges of aquatic habitats (Pianka and Vitt 2003. Lizards: Windows to the Evolution of Diversity. Univ. California Press, Berkeley. 333 pp.). Here, I report a predation event by a fish on *Eumeces fasciatus*.

At 1120 h on 31 July 2002, while fishing in Bay Creek, Pope County, Illinois (37°31'21"N, 88°39'15"W; elev. 164 m), I caught an adult (ca. 140 mm fork length) long-eared sunfish (*Lepomis megalotis*) that had eaten a juvenile *E. fasciatus* (29.2 mm SVL). The skink, still in the buccal cavity of the fish, appeared to have been recently consumed.

Known predators of *E. fasciatus* include various birds, mammals, snakes, and other lizards (Fitch 1954. Univ. Kansas Publ. Mus. Nat. Hist. 8:1–156), but predation by fish is unreported. Fish are atypical predators as *E. fasciatus* usually occupies forested habitats (Smith 1961. Illinois Nat. Hist. Surv. Bull. 28:1–298). The surrounding habitat of Bay Creek is oak-hickory forest and *E. fasciatus* is common on exposed rocks bordering the creek. The *L. megalotis* was caught along the bottom edge of a 10–12 m vertical sandstone cliff at a point where the creek undercut the rock. The skink likely fell into the water from the steep rock escarpment above the creek and was then consumed.

I thank Scott Hegrenes, John Petzing, Erin Shepard, Lindsay Shepard, and Laurie Vitt. The *E. fasciatus* (INHS 18552) was deposited in the Illinois Natural History Survey herpetology collection in Champaign, Illinois.

GAMBELIA WISLIZENII (Long-nosed Leopard Lizard). **NECROPHILIA**. Reports of mating or attempted mating with a dead conspecific or heterospecific individual are limited to the monogamous Australian skink, *Tiliqua rugosa* (How and Bull 1998. Herpetol. Rev. 29:240) and the Brazilian snake, *Tachymenis brasiliensis* (Amaral 1932. Mem. Int. Butantan 7:91–94). Here, I describe an occurrence of this behavior in *Gambelia wislizenii* from west-central Nevada, USA.

On 23 June 2004 at midday during color-manipulation experiments to investigate the role of breeding coloration in mate choice, I observed a male *G. wislizenii* attempting to mate with a brightly colored road-killed female in the South Magazine area of the Hawthorne Army Depot (HWAD), Hawthorne, Mineral Co. (38°30'0.8.3"N; 118°37'16.7"W; elev. ca. 1350 m). Judging from the carcass, the female had probably been killed within a few hours, but was clearly dead (her intestinal tract had been expelled from the impact and ants had begun scavenging the carcass). When found, the male was biting the right shoulder of the dead female, a behavior that is performed to initiate copulation (K. Fallahpour, unpubl. data). I watched the pair from a distance of 2–3 m for 5 min. The male froze in position and watched me for the duration of the observation. Thereafter, I approached the pair slowly and attempted to separate the male from the dead female by nudging him with a metal rod. After ca. 1 min of trying to separate them, the male dragged the dead female about 3 m away under a shrub on the road edge. At this point, the dead female was lying on her back, but the male maintained his grasp of her shoulder with his mouth. After an additional 5 min no other behavior was observed. I then approached the male again and began nudging him in an attempt to separate the pair. He released the female but remained next to her. I then introduced the male to a previously captured female *G. wislizenii* that was painted white to mask her breeding coloration. I placed the female ca. 1 m from the male using a cotton-thread harness attached to a thin monofilament line tethered to a fishing pole. The male immediately approached the tethered female and courted her: tongue flicked her, crawled on top of her, and bit her on the neck in an apparent attempt to initiate copulation. This continued for ca. 5 min. I then separated the two by removing the female. The male immediately ran back to the dead female, circled around her once, and bit her neck again. I watched him for an additional 5 min as he continued to attempt to copulate with the dead female.

During the breeding season, female *G. wislizenii* develop vibrant red-orange coloration on the sides of the head, body, and the ventral side of the tail (Montanucci 1967, Herpetologica 23:119–126). This bright coloration is absent in males and has been suggested to play a role in mate-choice decisions such as sex recognition, courtship stimulation, courtship rejection, or aggression avoidance (Cooper and Greenberg 1992, *In* Gans and Crews [eds.], Biology of the Reptilia, Vol. 18, pp. 298–422. Univ. Chicago Press, Chicago, Illinois). However, the role of breeding coloration in *G. wislizenii* has not been tested empirically, and anecdotal observations (summarized in Cooper and Greenberg, *op. cit.*) provide conflicting interpretations (receptive vs. unreceptive to mating). During this observation, the male attempted to copulate with a colored female just as readily as with a plain female. This would seem to support the hypothesis some investigators have suggested, i.e., that female breeding coloration in *G. wislizenii* might not be important to male mate selection (Fallahpour and Espinoza 2004. Integ. Comp. Biol. 43:847; Moore 1983. The Function of Orange Breeding Coloration in the Social Behavior of the Long-nosed Leopard Lizard [*Gambelia wislizenii*]. MS Thesis, Oregon State Univ., Corvallis, Oregon).

I thank the facilities managers at the HWAD for permitting me to conduct my research on the base, and the Society for Integrative

and Comparative Biology, the American Society of Ichthyologists and Herpetologists, and CSU Northridge for funding my research. R. E. Espinoza and M. P. Hayes provided helpful comments on the note.

Submitted by **KAMELIA FALLAHPOUR**, Department of Biology, California State University, Northridge, Northridge, California 91330-8303, USA; e-mail: kamelia.fallahpour@csun.edu.

GONATODES HUMERALIS (NCN). **OVIPOSITION SITE.** Most studies of reproduction in Brazilian lizards focus on the ecological aspects of the reproductive cycle. Oviposition sites are infrequently described. Among Amazonian *Gonatodes*, oviposition data exist only for *G. humeralis*. Eggs have been found behind loose bark on a tree trunk or base, between roots and among dead leaves, in termite nests, hidden below the surface in fine organic debris, concealed in a space below a stone, or in the hollow of a partly decayed tree branch (Avila-Pires 1995. Lizards of Brazilian Amazonia [Reptilia: Squamata]. Zoologische Verhandelingen. 706 pp. and references therein). Here, we describe a previously unrecorded oviposition microhabitat for *G. humeralis* in NE Brazil. Between 27 February and 11 March 2004, we found 10 eggs in the axils of five bromeliads (species not identified) in a mesophyllous secondary forest in the municipality of Urbanos Santos (3°12'28"S; 43°24'12"W; elev. 41 m), state of Maranhão. We found 1–3 *G. humeralis* eggs in each bromeliad (mean = 2; SD = 1), laid 15–23 cm (mean = 20 cm; SD = 2.6 cm; N = 10) above the ground. The eggs averaged 0.17 g in mass (SD = 0.02, range: 0.13–0.20), 7.4 mm in length (SD = 0.3, range = 7.0–8.0), and 6.4 mm in width (SD = 0.2; range: 6.0–6.6). The eggs were incubated in plastic containers and moistened every two days. Nine of the eggs hatched between 22 April and 01 May 2004; all were identified as *G. humeralis*. Hatchlings averaged 16.3 mm SVL (SD = 0.5, range: 15.5–16.9) and 0.13 g in mass (SD = 0.02, range: 0.11–0.15). The hatchlings were released after measurement.

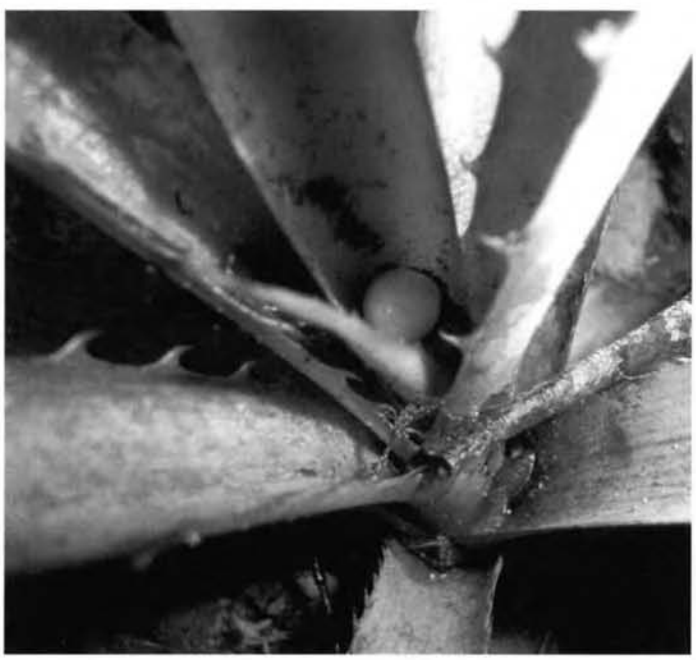

FIG. 1. *Gonatodes humeralis* egg in a terrestrial bromeliad axil.

Leaves of the oviposition bromeliads were characterized by sharp thorns along their margins (Fig. 1), which might provide protection for the eggs of *G. humeralis* against some predators. Accumulated water in these bromeliad axils also created a humid microhabitat that might minimize the risk of egg desiccation. Thus, the axils of some terrestrial bromeliads axils might offer a favorable incubation microhabitat for *G. humeralis* eggs. Data exist on *G. humeralis* using bromeliads at night (Nunes 2002. Ecologia da Floresta Amazônica-Curso de Campo, PDBFF-INPA, Manaus, 2nd ed., 163 pp.) and during the day up to heights of ca. 9 m (as *G. annularis*: Beebe 1944 cited in Avila-Pires 1995, *op. cit.*), but this is the first report of *Gonatodes* laying eggs in terrestrial bromeliads.

HEMIDACTYLUS MABOUIA (Tropical House Gecko). **PREDATION.** According to Vaughan (1976. J. Mammal. 57:227–248), the Heart-nosed Bat (*Cardioderma cor*) preys mainly on

FIG. 1. Heart-nosed bat, *Cardioderma cor*, eating a *Hemidactylus mabouia*. Photo by Leigh Ecclestone.

large, ground-dwelling beetles, but centipedes and scorpions and occasionally small bats are also consumed. Here, we report a direct observation of one Heart-nosed Bat feeding on a *Hemidactylus mabouia*.

While working on an informational exhibit on the harmless snakes of Kasigau at the Taita Discovery Center (TDC), Edwin Selempo, head naturalist for the TDC, heard the unmistakable sound of small bones being crunched overhead. Just 3.5 m above us was a *C. cor* hanging by its hindfeet from the thatch roof, munching on the hindquarters and tail section of what was left of a *H. mabouia*. By the time DW retrieved his camera, just the tail section above the cloaca could be seen protruding from the bat's mouth (Fig. 1). We watched the bat consume most of the tail as it flew from one part of the ceiling to another, avoiding two other heart-nosed bats attempting to steal the, as yet, uneaten tail. Observations were made at 0800 h on 30 July 2004, under the roof of an open-air classroom at the Taita Discovery Center, Rukinga Ranch, Taita/Taveta District-Coast Province, Kenya.

Submitted by **DAVID WOJNOWSKI**, Kent State University, 404 White Hall, P.O. Box 5190, Kent, Ohio 44242-0001, USA (e-mail: dwojnows@kent.edu); and **EDWIN SELEMPO**, Taita Discovery Center, P.O. Box 360, Voi, Kenya.

HOPLODACTYLUS MACULATUS (Common Gecko). **AGGREGATIONS**. Aggregative behavior has been observed in many squamate lineages (e.g., Brattstrom 1974. Amer. Zool. 14:35–49; Cooper and Gartska 1987. Copeia 1987:807–810; Gregory 2004. Herpetologica 60:178–186). However, lizard aggregations in diurnal retreat sites are rarely documented (Shah et al. 2003. Behaviour 140:1039–1052). Hence, we report here on the demographic structure of an unusually large (N = 94), diurnal aggregation of *Hoplodactylus maculatus* on a New Zealand island. On 17 May 2004 (autumn), we surveyed the *H. maculatus* occupying wooden, pest-control bait boxes as diurnal retreat sites. The bait boxes, deployed on the shoreline of Mana Island (40°40'S, 174°00'E) to control accidental rodent (e.g., *Rattus* sp.) incursions, ranged in size from 8.3 to 12.4 L, each with an internal central 0.5 L bait partition where the geckos commonly congregated beneath the bait holder. Fourteen bait boxes were surveyed between 1000 and 1500 h.

A total of 183 *H. maculatus* were found within the 14 bait boxes, with a mean of 13 ± 6 SE geckos per box. However, one bait box contained about half (N = 94) of all geckos captured, and two lacked geckos entirely. The aggregation of 94 geckos (39 juveniles, 11 males, 44 females) was very densely packed within the 0.5 L partition of the bait box, filling the entire area to capacity. Snout–vent length of adult males was slightly larger than adult females (72.7 ± 0.7 and 69.0 ± 0.7 SE mm respectively; $F_1 = 10.330$, $p = 0.002$) and did not differ between the large and smaller aggregations ($F_1 = 2.015$, $p = 0.160$). Overall, 36% of geckos in bait boxes were juvenile or sub-adult, 16% adult males and 48% adult females. The adult sex ratio varied substantially among bait box aggregations (range = 1:7 to 2:0 m:f). The only other lizard species found within the bait boxes was the skink *Oligosoma lineoocellatum*, one of which was found in a bait box with six *H. maculatus*, but not within the bait partition containing geckos.

Hoplodactylus maculatus, a moderate-sized (to 82 mm SVL) widespread, endemic, nocturnal gecko (Gill and Whitaker 2001. New Zealand Frogs and Reptiles, David Bateman, Auckland, New Zealand. 112 pp.), is frequently observed in diurnal aggregations. However, few aggregations have been documented, and details and measurements of aggregations have not been reported. For example, on Stephens Island, Cook Strait, up to 200 individuals were found beneath a corrugated iron sheet (Bauer 1990. Phylogenetic Systematics and Biogeography of the Carphodactylini [Reptilia: Gekkonidae]. Bonn. Zool. Monogr. 30, 217 pp.) and on Mana Island mixed age and sex groups of 10–15 individuals are common, with occasional large aggregations of >60 individuals (Whitaker 1993. Unpubl. report, New Zealand Department of Conservation, Wellington, New Zealand. 53 pp.).

Hoplodactylus maculatus is unlikely to aggregate because of a lack of suitable retreat sites, as the shore platform provides a complex habitat of rocks and logs that could be readily used. Aggregation, despite an abundance of retreat sites, could imply that the benefit may derive from social groups (Shah et al., *op. cit.*). However, the high variance in adult sex ratios suggests that aggregations may not always represent family groups or harems. Aggregative behavior in the nocturnal gecko *Nephrurus milii* might have evolved to provide facultative control over rates of thermal exchange (Shah et al., *op. cit.*), which offers a possible explanation for aggregations of *H. maculatus*. Other *Hoplodactylus* species have also been observed to aggregate in mixed size and sex class groups, including *H. duvaucelii* (Robb 1980. New Zealand Amphibians and Reptiles in Colour. Collins, Auckland, New Zealand. 128 pp.) and *H.* sp. 'Otago-Southland large' (Southey 1986. Unpubl. report, New Zealand Wildlife Service, Queenstown). Aggregation might be widespread and frequent in the genus *Hoplodactylus,* but its purpose needs clarification.

We thank C. L. Stephens and G. D. Timlin for their assistance in the field, A. H. Whitaker and C. H. Daugherty for comments on the draft, and R. A. Hitchmough for *Hoplodactylus* complex distribution lists. Our research was conducted with New Zealand Department of Conservation approval.

LEIOCEPHALUS CARINATUS ARMOURI (Northern Curly-tailed Lizard). **ENTANGLEMENT IN HUMAN-MADE MATERIALS**. Reports exist of reptiles caught in persistent, man-made debris. These materials result in deformity or death to freshwater turtles (Dietz and Ferri 2003. Herpetol. Rev. 34:56; McLeod 1994. Herpetol. Rev. 25:116–117; Odum 1985. Herpetol. Rev. 16:113) or tortoises (Engeman et al. 2004. Herpetol. Rev. 35:54–55); entanglement, injury, and death to upland snakes (see review in Stuart et al. 2001. Herpetol. Rev. 32:162–164); and, entanglement and death to desert lizards (Stuart et al., *loc cit.*). Here we add to these reports with an observation of *Leiocephalus carinatus armouri* found entangled in a metal ring.

At ca. 0830 h, 26 October 2003, a sunny day with a temperature ca. 25°C, one of us (CLD) observed an adult (71.0 mm SVL) *L. c. armouri* with a metal ring (22 mm exterior diameter, ca. 17–18 mm interior diameter) caught around its body just forward of the

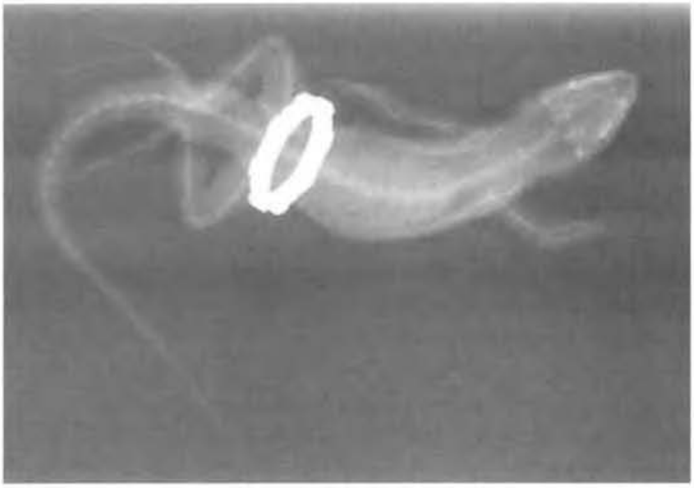

FIG. 1. Radiograph of *Leiocephalus carinatus armouri* entangled in a metal ring.

pelvic girdle (Fig. 1). The site was the parking lot of "Loggerhead Plaza" (14255 US Highway 1 in Juno Beach [Palm Beach Co.], Florida). The town of Juno Beach is within a relatively contiguous 90 km of the surveyed, occupied range of this exotic species in Florida (Smith and Engeman 2003. Florida Park Service Tech. Rep., Hobe Sound, Florida; Smith et al. *In press*. International Biodeterioration and Biodegradation).

The lizard was first observed basking on a curb in the parking lot. Under normal conditions, *L .c. armouri* is very fast fleeing when making an escape to a burrow or other refugium (Smith and Engeman, *loc. cit.*; Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida, Krieger Publishing Company, Malabar, Florida. 166 pp.). Although this lizard attempted to elude capture, mobility was hindered by the metal ring, and it was unable to fully extend its hind legs, causing it to drag the distal portion of its body.

We thank D. Hitzig, Busch Wildlife Sanctuary, for the radiograph of the specimen, and E. Cowan, Florida Park Service, for converting the radiograph to electronic format.

MICROLOPHUS QUADRIVITTATUS (NCN). **CANNIBALISM.** *Microlophus quadrivittatus* is a lizard restricted to the southern part of the coastal desert in Peru (Carrillo and Icochea 1995. Pub. Mus. Hist. Nat. UNMSM 49:1–27). Its diet consists of intertidal invertebrates, marine algae, and some dipterans (Donoso-Barros 1966. Reptiles de Chile. Ediciones Univ. Chile, Santiago. 458 pp.; Perez and Jahncke 1998. Bol. Inst. Mar del Peru 17:81–86), but cannibalism is unreported. Here, we provide the first report of cannibalism in this species.

At 1200 h on 23 March 2000, we captured an adult male *M. quadrivittatus* (146 mm SVL, 85 g, MHNSM 18598) among rocks near the sea shore at Coles Point (17°42'S; 71°22'W; elev. 5 m), Departamento de Moquegua, Peru. The stomach of the adult male *M. quadrivittatus* contained a conspecific juvenile (ca. 70 mm SVL, 8.9 g., MHNSM 18599). The juvenile lacked apparent bite marks, but its tail was partially broken. Additionally, we examined the stomach contents of 20 other *M. quadrivittatus* from this same locality, but this was the only record of cannibalism among them (unpubl. data).

Adults and juvenile of *M. quadrivittatus* show differences in their microhabitat use that would reduce opportunities for cannibalism (Donoso 1948. Bol. Mus. Nac. Hist. Nat. 34:213–216), but the frequency of this phenomenon remains unknown.

Both specimens were deposited in the Department of Herpetology collection of the Museo de Historia Natural de la Universidad Nacional Mayor de San Marcos, Lima, Peru. We thank Carlos Frederico D. Rocha and Edgar Lehr for beneficial comments on versions of this manuscript.

NEOSEPS REYNOLDSI (Sand Skink). **LONGEVITY**. Skinks in general are relatively long-lived (e.g., *Eumeces fasciatus* can live up to 10 years; Fitch 1965. Univ. Kansas Mus. Nat. Hist., Misc. Publ. [42]:1–60). Fossorial skinks have exceptionally low metabolic rates (Andrews and Pough 1985. Physiol. Zool. 58:214–231; Withers 1981. Copeia 1981:197–204) and thus might be expected to be particularly long-lived. *Neoseps reynoldsi* is a fossorial skink for which estimates of longevity range from 3 (Telford 1959. Copeia 1959:110–119) to 7 years (Sutton 1996. MSc thesis, Univ. of South Florida, Tampa. 45 pp.). Here, we present mark-recapture information on a *N. reynoldsi* from Archbold Biological Station, Highlands Co., Florida that exceeds previous estimates of longevity.

On 11 March 2002, we captured a marked (left foreleg removed) *N. reynoldsi* (62 mm SVL, 1.3 g) under a coverboard. During 1994 an individual (54 mm SVL) at this study site was given this mark. No individuals at this site have been marked since 1994. *Neoseps reynoldsi* have greatly reduced limbs with one (forelegs) or two (hindlegs) small digits per foot. That the mark was from natural loss is unlikely because, 1) the entire left foreleg was removed, and 2) of ~100 *N. reynoldsi* captured by KGA none has ever been missing entire limbs. Mark-recapture data suggest that *N. reynoldsi* reach 54 mm SVL in the second or third year of life (Sutton, *op. cit.*). If this individual was at least two years old in 1994, it must be at least 10 years old now. The long life span of *N. reynoldsi* might be explained in part by life history (clutch size of two, reproducing at most once/year; Ashton, unpubl. data) and physiological correlates of fossoriality (i.e., low metabolic rate; Andrews and Pough, *op. cit.*; Withers, *op. cit.*).

Permit WX01623 from the Florida Fish and Wildlife Conservation Commission to KGA made these observations possible.

Submitted by **BLAKE M. MENEKEN, ANNA C. S. KNIPPS, JAMES N. LAYNE,** and **KYLE G. ASHTON**, Archbold Biological Station, 123 Main Drive, Venus, Florida 33960, USA (e-mail [KGH]: kashton@archbold-station.org).

OLIGOSOMA LINEOOCELLATUM (Spotted Skink). **LONGEVITY, SITE FIDELITY.** New Zealand reptiles are widely known for their great longevity and low reproductive output (Cree 1994. New Zealand J. Zool. 21:351–372; Daugherty et al. 1993. TREE 8:437–442). For example, Tuatara (*Sphenodon punctatus*) have a minimum longevity of 81 yrs (N. Nelson, pers. comm.), geckos (*Hoplodactylus duvaucelii* and *H. maculatus*) live for at least 36 yrs (Thompson et al. 1992. J. Royal Soc. New Zealand 22:123–130; Bannock et al. 1999. New Zealand J. Ecol. 23:101–103), the skink *Cyclodina whitakeri* has a minimum longevity of 16–18 yrs (Towns and Ferreira 2001. Biol. Cons. 98:211–222), and the skink *Oligosoma suteri* can live for a minimum of 12 yrs (Towns and Ferreira, *op. cit.*). However, conclusions about the generality of great longevity in New Zealand reptiles are based on limited data; few records exist for many free-living reptile species because of the lack of long-term mark-recapture studies on many New Zealand reptiles. Here, we augment longevity information on New Zealand reptiles with a report for the spotted skink, *O. lineoocellatum.*

During studies of skink habitat use, *O. lineoocellatum* were individually marked on two Cook Strait islands: North Brother Island in 1999 (Phillpot 2000. MSc thesis. Victoria University of Wellington) and Stephens Island in 1991–1992 (East et al. 1995. New Zealand J. Zool. 22:249–261). Six of the 332 skinks marked on North Brother Island were recaptured by JMH in 2004. All six skinks recaptured were marked as adults in 1999 (SVL > 62.1 mm; Spencer et al. 1998. New Zealand J. Zool. 25:457–463). As New Zealand skinks are thought to take ca. 3 yrs to reach maturity (Whitaker 1976. Forest and Bird 202:8–11), our most conservative estimate of longevity for *O. lineoocellatum* is 8 yrs in the wild. New Zealand lizards often exhibit strong site fidelity (e.g., Barwick 1959. Trans. Royal Soc. New Zealand 86:331–380), which is supported by the recapture of five of the six skinks on North Brother Island within 15 m of their initial capture sites. However, one individual was recaptured ca. 60 m from its original capture point, which demonstrates that limited dispersal is possible. On nearby Stephens Island, 360 *O. lineoocellatum* were individually marked in 1991–1992. No marked lizards were recaptured by CLS despite intensive pitfall-trapping at the same sites in November 2002 and March 2003 in which 397 and 340 animals, respectively, were caught in the same grids, and the recapture rate reached 80% by the end of each survey. As these skinks were not permanently marked, it is not possible to investigate site fidelity across seasons. However, during a trapping season, 70% of recaptured skinks (marked by non-permanent marker pen) were recaptured in the same trap, and 96% were recaptured within 7 m of initial capture. Because of strong site fidelity and the capture of a large number of *O. lineoocellatum* during the re-survey, a reasonable chance exists that skinks marked in 1991–1992, and still surviving, would have been recaught. We therefore suggest that maximum longevity in the wild is less than 14 yrs for *O. lineoocellatum.*

Our finding that *O. lineoocellatum* live for 8 to <14 yrs in the wild agrees with findings for other New Zealand skinks (e.g., Towns and Ferreira, *op. cit.*). In comparison to other skinks (e.g., Read 1998. Aust. J. Zool. 46:617–629), New Zealand species are relatively long-lived with low reproductive output, possibly as a result of the physiological limitations of living at colder temperatures (Cree, *op. cit.*) and historical lack of predation by mammals (Daugherty et al., *op. cit.*).

We thank the Te Atiawa and Ngati Koata people and the New Zealand Department of Conservation for supporting our research and numerous field assistants for helping to collect data. Financial support was provided by the Foundation for Research, Science and Technology and a Society for Research on Amphibians and Reptiles in New Zealand herpetological research award (scholarships to JMH).

OPHISAURUS ATTENUATUS LONGICAUDUS (Slender Glass Lizard). **CLUTCH SIZE and BROODING**. Reproductive data among North American glass lizards (*Ophisaurus*) has been obtained largely from *O. ventralis* (e.g., Fitch 1989. Occas. Pap. Mus. Nat. Hist. Univ. Kansas 125:1–50; Vinegar 1968. Bull. California Acad. Sci. 67:65–68; Witz and Wilson 1993. Florida Field Nat. 21:36–37). Except for Fitch (*op. cit.*), who reported clutch sizes of 5–16 for *O. a. attenuatus* in Kansas, and Mount (1975. The Reptiles and Amphibians of Alabama. University of Alabama Press. Tuscaloosa, Alabama. 347 pp.), who noted two gravid *O. a. longicaudus* from Alabama contained 5 and 10 oviductal eggs, reproductive data on *O. attenuatus* are lacking. Hence, here I report the first record of clutch size, egg size, and brooding behavior in *O. a. longicaudus* from Tennessee, USA.

At 1045 h on 2 July 2004, I discovered an adult female slender glass lizard with eggs (Fig. 1) in a depression under a wooden cover board in the southwestern portion of Arnold Air Force Base in Franklin County (35°21'22"N, 86°09'00"W; elev. 335 m). To minimize disturbance, neither the female nor the eggs were physically manipulated; only eggs that could be measured without handling were used to estimate egg size. Using a single data logger-linked thermocouple, air and substrate temperatures were measured at four locations 90° to each other ca. 0.5 m from the nest, and taken ca. 7 cm above and 3 cm below the substrate, respectively. I also obtained a nest temperature by positioning the thermocouple between the eggs and the body of the female.

The nest was located in a young, open Loblolly Pine (*Pinus taeda*) forest with < 25% canopy cover and a graminoid-dominated groundcover. Located ca. 10 m from the edge of an adjacent closed canopy pine forest, the nest was ca. 20 m from a seldom-used gravel road separating this area from a 2-yr-old clear-cut containing early successional vegetation comprised primarily of grasses and woody debris.

The female, ca. 1 m total length, was coiled around eight eggs; three eggs measured were estimated to be 2.3 x 1.4 cm. At 1100 h,

the air and substrate were 24.2°C and 25.2°C, respectively. The nest temperature, taken within 1 min of the substrate temperatures, was 26.7°C. The female remained motionless during measurements of egg sizes and temperatures.

Clutch size is within the range reported for *O. attenuatus* (Fitch, *op. cit.*; Mount, *op. cit.*), and both clutch size and egg sizes observed were similar to those for the congeneric *O. ventralis* (Gras-Riedel 1993. Salamandra 28:161–170; Schwab 1992. Herpetol. Rev. 23:60; Witz and Wilson, *op. cit.*). Further, the female being coiled around the eggs is a characteristic part of what has been termed brooding among North American *Ophisaurus* (Mount, *op. cit.*). This behavior is thought to be maintained through hatching in late summer-early autumn (Mount, *op. cit.*), but its function is poorly understood. Smith (1946. Handbook of Lizards: Lizards of the United States and Canada. Comstock Publ. Co., Inc. Ithaca, New York. 557 pp.) suggested that brooding in *Ophisaurus* increases nest temperature, presumably enhancing offspring development. However, given the small temperature differences (0.2–0.4°C) previously observed between the body of the female and the substrate, a thermoregulatory benefit was deemed unlikely (Noble and Mason 1933. Amer. Mus. Novitates 619:1–21; Vinegar, *op. cit.*). My recording of a nest temperature at least 1.5°C higher than the substrate temperature may restore confidence in the thermoregulatory importance of brooding, however demonstration that it enhances embryonic development is needed. Based on female *Ophisaurus* failing to protect their eggs after being exposed to potential nest predators, Noble and Mason (*op. cit.*) concluded that it was also doubtful that females remain with the eggs for the sole purpose of defense. The lack of female response I observed during intrusion to the nest might support this idea, but does not exclude the possibility that remaining with the eggs may deter small predators.

I thank Arnold Air Force Base for providing support for field work.

OPHISAURUS VENTRALIS (Eastern Glass Lizard) **PREDATION.** Atypical encounters can result in opportunistic predation on unusual reptilian prey (Smith and Engeman 2003. Herpetol. Rev. 34:245–246; Woodin and Woodin 1981. Florida Field Nat. 9:64). Using tactile probing, the White Ibis (*Eudocimus albus*) feeds mainly on fiddler crabs and insects, but also selectively consumes crayfish, crabs, insects, and frogs in greater proportions during nesting season (Kushlan and Bildstein 1992. *In* A. Poole and F. Gill [eds.], The Birds of North America. pp. 1–20. The Academy of Natural Sciences, Philadelphia; and AOU, Washington, DC.). Here, we report an instance of predation by White Ibis on an *Ophisaurus ventralis* in southeastern Florida.

At ca. 0845 h, 24 February 2004, a cloudy day with an air temperature ca. 23°C, JAM observed five adult White Ibis foraging in the lawn and sandy patches below a palm tree in a backyard in Vero Beach (27°38.444'N, 80°25.071'W; elev. 4 m). The ibises were soil-probing with their bills when one individual stood up with what was clearly an *O. ventralis* of about 45 cm (total length) in its bill. The ibis tried to reposition the lizard for swallowing when JAM inadvertently disturbed it; consequently, it flew off with the glass lizard still in its bill.

A small colony of *O. ventralis* has existed under the deck of the house, and in the leaf litter in this backyard since at least 2001 (unpubl. data). The event was noteworthy because white ibises are largely crustacean diet-specialized wading birds that were foraging in a terrestrial situation, and captured a fossorial reptile. The typical predators of *Ophisaurus* include snakes, hawks, and carnivorous mammals (Means 1992. *In* Moler [ed.], Rare and Endangered Biota of Florida, pp. 247–250, University Press of Florida, Gainesville; Beane 1995. Wildlife Profiles, NC Wildlife Resources Commission, Raleigh, North Carolina. 2 pp.). Likewise, we know of no similar depredation reports for *O. ventralis* in the literature.

SMITH**, Florida Department of Environmental Protection, Florida Park Service, 13798 S.E. Federal Highway, Hobe Sound, Florida 33455, USA; and **RICHARD M. ENGEMAN**, National Wildlife Research Center, 4101 LaPorte Ave., Fort Collins, Colorado 80521-2154, USA.

PHELSUMA LATICAUDA LATICAUDA (Golden Dust Day Gecko). **NECTARIVORY.** *Phelsuma l. laticauda*, a highly territorial, arboreal day gecko endemic to Madagascar and the Comoros Islands, has been introduced to Farquhar Island (southern Seychelles) and Hawaii, where it can reach locally high densities (McKeown 1996. A Field Guide to the Reptiles and Amphibians of the Hawaiian Islands. Diamond Head Pub. Inc. California. 172 pp.). Here, I report on nectar consumption and potential pollination behavior in introduced Hawaiian *P. l. laticauda*.

Between 1600 and 1900 h on 27 July 2001, several *P. l. laticauda* were observed in Kona, on the west coast of the island of Hawaii (19°36'00"N, 155°59'25"W; elev. ca. 30 m), drinking nectar from flowers of *Strelizia nicolai* (Strelitziaceae) and coming in contact with both the stamens and stigmas of *S. nicolai*.

Strelizia nicolai was also introduced to Hawaii from subtropical

South Africa for ornamental purposes (Hensley et al. 1998. Bird of Paradise. Univ. Hawaii Coop. Ext. Pub. OF-27, Honolulu, Hawaii), and the behavior I observed suggests that *P. l. laticauda* has the potential to facilitate its pollination. Flower visitation and pollination in the wild has been reported in other species of *Phelsuma* (Nyhagen et al. 2001. J. Trop. Ecol. 17:755–761 and references therein), and the genus is known to be highly nectarivorous and frugivorous in captivity, a pattern that the appellation "hummingbirds of lizarddom" reflects (Rundquist 1995. Day Geckos. TFH Publications, Inc., Neptune City, New Jersey. 64 pp.). This, together with a largely island-based distribution where the diversity of pollinators is usually low (Olesen and Jordano 2002. Ecology 83:2416–2424), suggests that specialized plant-lizard interactions worthy of research attention might occur in the genus *Phelsuma*.

SCELOPORUS OLIVACEUS (Texas Spiny Lizard). **ECTOPARASITISM**. The chigger mite *Eutrombicula alfreddugesi*, the most frequent cause of mite infestation in the United States, burrows into the outer skin, producing a characteristic itch and associated inflammation (Potts 2001. Postgrad. Med. 110:57–64). Several studies have documented infestations of this mite in sceloporine lizards (*Sceloporus undulatus*: McAllister 1980. Proc. Arkansas Acad. Sci. 34:125; *S. grammicus microlepidotus* and *S. palaciosi*: Gadsden 1988. Acta Zool. Mex. [n.s.] 30:21–31); however, infestation of *S. olivaceus* is unreported. Here, we report chigger mite parasitism in *S. olivaceus* from northern México.

In October 2003, during a study on the herpetofauna at the Parque Ecológico Chipinque in the municipalities of Garza García and Monterrey, Nuevo León (25°34'50"N, 100°21'55"W; elev. 1365 m), we captured 13 adult *S. olivaceus* with a noose or by hand. Data obtained for each lizard included sex (hemipenal eversion used to identify males), snout–vent length (SVL, to nearest mm), weight (W, with a 30-g Pesola™ spring scale) and the total number of chigger mites carried (T_m). To obtain the latter, we carefully examined lizards, but especially the neck pockets, axillae, and postfemoral pleats. The mites were removed at the place of capture using wetted cotton swabs. The red color of the mites allowed counting them on the surface of the cotton with a magnifying glass and collecting them. Lizards were released at the place of capture. We used Talleklint-Eisen and Eisen criteria (1999. Exp. Applied Acarology 23:731–740) to categorize infestation intensity: low (1–6 mites per individual), moderate (7–15), or high (> 15). A Kolmogorov-Smirnov goodness of fit test revealed SVL, W, and T_m to be normality distributed, so we used t-tests to compare means of SVL, W, and T_m between males and females. We also carried out regression analysis between SVL and T_m, and W vs T_m for both sexes. We assumed all tests to be significant at $a = 0.05$; measurements are reported as mean ± SE.

We captured 13 *S. olivaceus* (7 males and 6 females), all of which carried chigger mites. Mean SVL (86.6 ± 7.1 mm) and W of females (23.5 ± 4.6 g) was significantly greater than the mean SVL (44.8 ± 6.1 mm) and W (5.1 ± 2.7 g) of males (SVL: t = 3.40, $P = 0.007$; W: t = 4.42, $P = 0.001$). Of the 7 males, one each showed a low and a moderate infestation, but in the remainder (71.4%; N = 5), infestation was high. Of the 6 females, half had low and half had high infestations. Mean T_m for males (47.5 ± 12.7; range: 3–100) and females (23.1 ± 10.5; range: 1–60) were similar (t = 1.44; $P = 0.170$). We found no relationship between SVL and T_m for males (r = 0.26; $F_{1,5} = 0.38$; $P = 0.564$; N = 7) and females (r = 0.10, $F_{1,4} = 0.04$; $P = 0.847$; N = 6); or between W and T_m for each sex (males: r = 0.59, $F_{1,5} = 2.72$; $P = 0.164$; N = 7; females: r = 0.70, $F_{1,4} = 3.92$; $P = 0.119$; N = 6). Mites were found exclusively in the neck pockets of males and females.

No significant relationship was found between SVL and W or T_m in males or females, so mite infestation might not reduce the physical condition of *S. olivaceus* as Schall et al. (2000. J. Herpetol. 34:160–163) and Vrcibradic et al. (2000. Herpetol. Rev. 31:174–175) discuss in their respective studies involving *S. occidentalis* and *Geckobiella texana*, and *Mabuya macrorhyncha* and *E. alfreddugesi*. However, our samples were small, and more data will be required to verify the lack of relationship. Mites being concentrated in neck pockets for both sexes supports the idea that neck pockets may be preferred when space exists to attach inside them. This can benefit the host as functionally important areas, like the eardrums and axillae (Salvador et al. 1999. Herpetologica 55:1–7) are not used.

We thank Nixon Wilson (University of Northern Iowa) for confirming the mite identification, Gabriel Mata Flores, Andres Rios Saldaña, and David Aguillón for help in the field, and Marc P. Hayes for suggestions on the manuscript.

SCELOPORUS UNDULATUS UNDULATUS (Eastern Fence Lizard). **KYPHOSIS AND SCOLIOSIS**. Kyphosis and other malformations of the vertebral column like scoliosis are well known in turtles (e.g., Nixon and Smith 1949. Turtox News 27:28–29; Rhodin et al. 1984. British J. Herpetol. 6:369–373; Stuart 1996. Bull. Chicago Herpetol. Soc. 31:60–61) and occasionally reported for snakes usually as a result of developmental malformations (Frye 1991. *In* Frye [ed.], Biomedical and Surgical Aspects of Captive Reptile Husbandry, Vol. 2, pp. 393–420, Krieger Publ. Co., Mabalar, Florida; Gray et al. 2003. Bull. Chicago Herpetol. Soc. 38:4–6). Most malformations reported for lizards include bifurcations of the tail that usually are results of injuries (Blair 1960. The Rusty Lizard. Univ. Texas Press, Austin, Texas, 185 pp.; Scott 1982. Herpetol. Rev. 13:46; Smith 1946. Handbook of Lizards. Cornell Univ. Press, Ithaca, New York, 557 pp.). Reports of other types of abnormalities are rare. Tinkle (1967. Misc. Publ. Mus. Zool. Univ. Michigan 132:1–182) listed a juvenile female *Uta stansburiana* with a crooked tail, apparently a case of scoliosis. In this note, we describe the first case of a sceloporine lizard with both kyphosis and scoliosis.

On 25 September 2002, we caught a juvenile female *Sceloporus undulatus* (48 mm SVL, 78 mm tail, 6.8 g) on leaf litter in mixed hardwoods and pine adjacent to a vernal pool in the Colonial

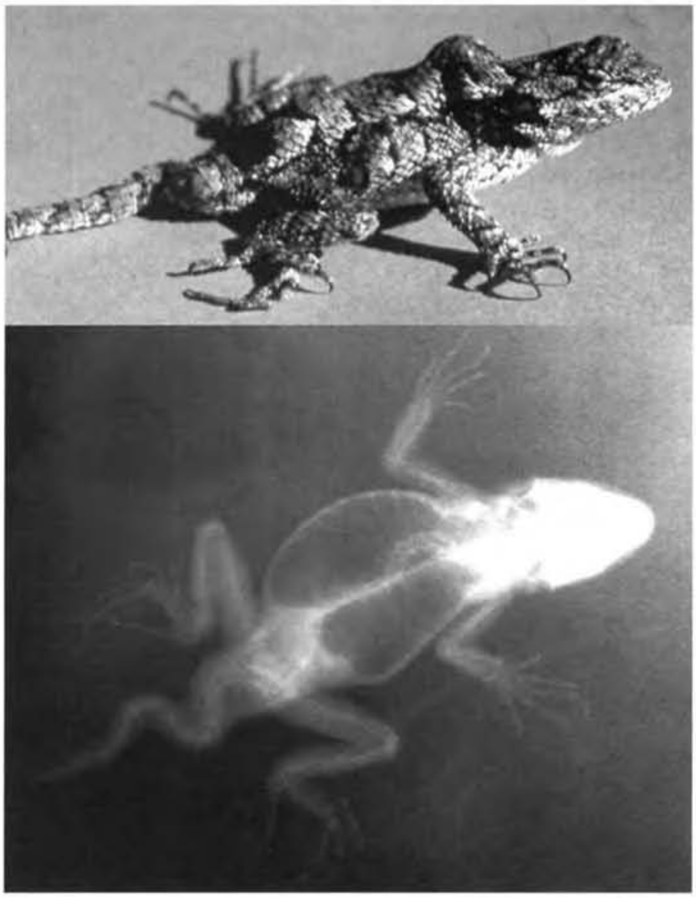

FIG. 1. *Sceloporus undulatus* from Virginia with multiple kyphosis and scoliosis.

National Historical Park, 4.3 km S Yorktown, York County, Virginia (37°11'39"N, 76°30'45"W; elev. 13 m). She exhibited two vertical curvatures of the spine (kyphosis), one behind the pectoral region and one over the pelvic girdle (Fig. 1). The anterior one was also curved to the left and the posterior one was curved to the right. In addition, her tail had three, alternating lateral curves near the base (scoliosis). This lizard experienced no obvious limitations in mobility or prey capture as she was maintained in captivity on live crickets until 19 June 2003. She actively pursued all prey introduced into her cage and grew 14 mm SVL during this period. We released her on that date at the site of capture.

We thank Judy Greene of Savannah River Ecology Lab for helping to secure the radiograph.

Submitted by **JOSEPH C. MITCHELL**, Department of Biology, University of Richmond, Richmond, Virginia 23173, USA (e-mail: jmitchel@richmond.edu); and **C. TODD GEORGEL**, 8720 Higgenbothom Place, Richmond, Virginia 23229, USA.

SCINCELLA LATERALIS (Ground Skink). **ARBOREAL BEHAVIOR**. Ground Skinks are active foragers that prey on small terrestrial invertebrates (Brooks 1967. Ecol. Monogr. 37:71–87), but the behavioral ecology of this species is not well known (Akin 1998. Can. J. Zool. 76:87–93). In mixed hardwood forests of eastern North America, Ground Skinks typically are described as being diurnal, generally occurring in leaf litter (Mitchell 1994. The Reptiles of Virginia. Smithsonian Institution Press. 352 pp.). Here, we report an observation of nocturnal foraging in an arboreal microhabitat by this typically diurnal, terrestrial species.

While collecting harvestmen (Arthropoda, Sclerosomatidae) on an undeveloped forested portion on the Virginia Wesleyan College campus, Norfolk/Virginia Beach, Virginia (36°51'52"N, 76°11'34"W; elev. 4 m), we observed an adult (41 mm SVL) male *S. lateralis* actively foraging on small flying insects while climbing a tree. The habitat is mesic mixed hardwood forest with a tree canopy dominated by White Oak (*Quercus alba*), Southern Red Oak (*Quercus falcata*), and Red Maple (*Acer rubrum*); a dogwood (*Cornus florida*) understory; and an herb layer of Poison Ivy (*Rhus toxicodendron*), English Ivy (*Hedera helix*), Sassafras (*Sassafras albidum*), and occasional patches of Mayapple (*Podophyllum peltatum*). Ground Skinks occur, but are infrequent, in this habitat.

On 9 June 2004 at 2100–2115 h EST, we observed a ground skink slowly climbing the trunk of a small (20 cm diam) Black Gum (*Nyssa sylvatica*). When first spotted, the lizard was 80 cm above the ground. Using a red light headlamp, we observed the skink slowly move to a deep scar in the trunk at a height of 122 cm. During its ascent, the skink repeatedly moved its head laterally and tongue flicked frequently. Periodically, tongue flicks were followed by swift head movements that seemed directed at tiny flying insects hovering or landing near the lizard. During our 15-min observation period, the lizard approached several small black ants, juvenile wood roaches, and small harvestmen. It repeatedly attempted to capture the small flying insects, but ignored the larger arthropods. After it stopped climbing, we captured the lizard to measure it and verify its gender. We subsequently released it at the base of the tree.

Our observation is the first report of *S. lateralis* actively foraging at night in an arboreal microhabitat. This observation implies that these lizards might opportunistically climb plants in a manner similar to that reported for other typically terrestrial species, e.g., *Plethodon cinereus* (Jaeger 1978. Copeia 1978:686–691).

TOWNSEND, JR.** (e-mail: vtownsend@vwc.edu), **VITILLIA WILTSHIRE**, Department of Biology, Virginia Wesleyan College, 1584 Wesleyan Drive, Norfolk/Virginia Beach, Virginia 23502, USA; and **JONATHAN A. AKIN**, Department of Biological Sciences, Northwestern State University, Nachitoches, Louisiana 71497, USA.

TRACHYLEPIS SPILOGASTER (Kalahari Tree Skink). **ENDOPARASITES.** *Trachylepis spilogaster* occurs in arid savannah from Kimberley and Lower Orange River in Northern Cape Province, through Botswana and Namibia to southern Angola (Branch 1998. Field Guide to Snakes and other Reptiles of Southern Africa, Ralph Curtis Books, Sanibel Island, Florida. 399 pp.). Goldberg and Bursey (2001. Onderstepoort J. Vet. Res. 68:143–147) reported the cestode *Oochoristica truncata* and the nematodaes *Parapharyngodon rotundatus, Spauigodon petersi, Thubinaea fitzsimonsi,* and unidentified ascarid larvae from *T. (Mabuya) spilogaster* from Botswana. The purpose of this note is to report an additional species of Nematoda, *Abbreviata paradoxa,* in *T. spilogaster.*

Coelomic cavities of 334 (201 from Botswana, 133 from Republic of South Africa) were examined for helminths. One

female *T. spilogaster* collected 12 May 1970 (73 mm SVL, LACM 80927) from Cape Province, Republic of South Africa contained one nematode. The nematode was cleared in a drop of concentrated glycerol on a glass slide, cover-slipped, examined under a compound microscope, and identified as a female *Abbreviata paradoxa.* It was deposited in the United States National Parasite Collection, Beltsville, Maryland as USNPC (95027).

The physalopterid nematode, *A. paradoxa* is previously known from the scincids, *Trachylepis (Mabuya) occidentalis* and *Trachylepis (Mabuya) striata* from South Africa (Goldberg and Bursey, *op. cit.*), the varanids *Varanus albigularis* from South Africa (Linstow 1908. Denk. Med. Natur. Ges. 13:19–28), *Varanus bengalensis* from India (Baylis 1939. The Fauna of British India, including Ceylon and Burma. Nematoda. Vol. II. Taylor and Francis, London, 408 pp.), and *Varanus griseus* from Russia (Andrusko and Markov 1956. Vest. Leningrad Univ., Biol. Ser. 21:61–71), and the colubrid *Psammophis sibilans* from Sudan (Ortlepp 1922. Proc. Zool. Soc. London 72:999–1107). Members of the nematode family Physalopteridae utilize a wide variety of arthropods as intermediate hosts (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission, 2nd ed. CABI Publishing, Oxon, U.K. 650 pp.), which the vertebrate host then typically consumes to complete the physalopterid life cycle. *Trachylepis spilogaster* is a new host record for *A. paradoxa.*

BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

VARANUS CF. GOULDII (Gould's Monitor). **RITUAL COMBAT.** Observations of male-male fighting in free-ranging monitors are rare. In particular, male ritual combat has only been partially described from southwestern Australia (Thompson and Withers 1992. West Austr. Nat. 19:21–29). Here we describe a case of ritual combat in *V. cf. gouldii* from northeastern Australia.

Our observations were made at Castle Hill, Townsville, Queensland (19°15'0"S, 146°48'40"E; elev. 142 m). At 1700 h on 16 January 2004, we came upon two *V. cf. gouldii* engaged in classic varanid ritual combat (*fide* Auffenberg 1994. The Bengal Monitor. Univ. Florida Press, Gainesville, 561 pp., for captive *V. nebulosus*). When first seen the two monitors were in a bipedal stance on the road shoulder (Fig. 1). They were engaged in a brachial embrace, twisting and turning in a wrestling match that continued for ca. 7 min. The lighter-colored male (Male 1) then managed to climb higher on his opponent (Male 2) and push him into the body-arch position (see Auffenberg, *op. cit.*). Within < 2 min Male 1 had pushed Male 2 to the ground on his back, although they still remained in brachial embrace. Male 2 then struggled free, but immediately returned to bipedal stance, and another bout of wrestling began. By this time, road traffic was backing up as a crowd had gathered and several tourists approached the lizards for photo shots. The monitors stopped, apparently noticing the humans for the first time. They dropped to the ground and ran off in the same direction into the nearby eucalypt woodland. Total observation time was about 15 min.

FIG. 1. Adult males of *Varanus cf. gouldii* in bipedal stance during ritual combat at Castle Hill, Townsville, Queensland.

Submitted by **HAROLD DE LISLE**, P.O. Box 1975, Twentynine Palms, California 92277, USA (e-mail: hdelisle@earthlink.net); and **NYOMAN DEWANTARA**, James Cook University, Townsville, Queensland 4811, Australia.

SERPENTES

ACRANTOPHIS DUMERILII (Dumeril's Ground Boa). **DIET**. Madagascar is well known for the presence of a conspicuous boid fauna including *Sanzinia madagascariensis, Acrantophis madagascariensis,* and *A. dumerilii* (Vences and Glaw 2003. Salamandra 39:181–206). The adults of these species prey mainly upon mammals and birds, whereas juveniles are believed to prey upon lizards and frogs, as is the case for many other boids (Glaw and Vences 1994. A Fieldguide of the Amphibians and Reptiles of Madagascar. Vences and Glaw Verlag, Cologne. 480 pp.). Here we report predation by *Acrantophis dumerilii* on an insect. On 22 January 2004 at 2130 h we found a female *A. dumerilii* within the Isalo Massif in central-southern Madagascar next to Ilakaka (Ranohira Fivondronana, Fianarantsoa Faritany, 22°49.85'S and 45°17.75'E, 680 m elev.). The snake (ca. 1700 mm TL, and ca. 3.5 kg) was coiled around its prey, on the dry bed of an intermittent river. We delicately unrolled the specimen and discovered a Madagascan Giant Hissing Cockroach, *Gromphadorhina*

portentosa (Museo Regionale di Scienze Naturali, MRSN-FAZC 11962). The roach measured 70 mm TL and weighed 10 g. Our observations suggest that giant hissing cockroaches are quite common in this area. Predation by large constrictors upon insects was until now undescribed, and this observation suggests that *A. dumerilii* opportunistically forages.

We thank Jasmin E. Randrianirina for assistance and the Nando Peretti Foundation for funding.

Submitted by **FRANCO ANDREONE** (e-mail: f.andreone@libero.it) and **VINCENZO MERCURIO,** Museo Regionale di Scienze Naturali, Via G. Giolitti, 36, I-10123 Torino, Italy.

ADELPHICOS QUADRIVIRGATUS NEWMANORUM (Newman's Earth Snake). **PREDATION.** Invertebrate predation on snakes has only infrequently been documented or photographed (Bayliss 2001. Herpetol. Rev. 32:49; Greene 1988. *In* Gans and Huey [eds.], Biology of the Reptilia, Vol.16, Ecology B, Defense and Life History, pp 1–152. Alan R. Liss, New York; Hill and Phillipps 1981. A Colour Guide to Hong Kong Animals. Government Printer, Hong Kong. 281 pp.; Mayne and Babb 2004. Herpetol. Rev. 35:399; McCormick and Polis 1982. Biol. Rev. 57:29–58; McKeown 1963. Australian Spiders. Angus and Robertson, Sydney. 287 pp.; Owens 1949. Herpetologica 5:148). One author found a snake in a spider web (Zippel and Kirkland 1998. Herpetol. Rev. 29:46). Here we describe a spider feeding on a snake carcass.

The following observations were made 19 June 2003 during a herpetological survey in the Sierra Madre Oriental in the Area Natural Protegida La Estanzuela (25°31'54"N, 100°16'38"W; 900 m elev.), near Monterrey, Nuevo Leon, México. A dead female *Adelphicos quadrivigatus newmanorum* (UNAL 6233; 370 mm TL) was found suspended in a spider's web about 20 cm above a small, nearly perennial stream (ca. 1–3 m wide and 60–150 cm deep). An adult female *Dolomedes tenebrous*, an aquatic spider in the family Pisauridae, was eating the snake's carcass. Pisaurid spiders (Nursery Web or Fishing Spiders) run across water surfaces and dive after prey. They live near the banks of creeks and ponds. The spider had consumed much of the snake's flesh in an area extending from ca. 33 to 40 mm posterior of the snout. This specimen represents only the second *A. q. newmanorum* collected in the state of Nuevo Leon (Contreras 1989. Publ. Biol. Fac. Ciencias Biol., Univ. Auton. Nuevo Leon 3:35–36). We thank Wade C. Sherbrooke for reviewing this note.

FIG. 1. *Dolomedes tenebrous* consuming *Adelphicos quadrivigatus*.

AGKISTRODON PISCIVORUS (Western Cottonmouth). **FORAGING BEHAVIOR**. In a drained reservoir on Loggy Bayou Wildlife Management Area (Bossier Parish, Louisiana, USA) on 24 May 2004 we startled a young-of-the-year (40–60 mm) *Rana sphenocephala* (Southern Leopard Frog). During its escape the frog crossed the path of a 400–500 mm *Agkistrodon piscivorus*. The snake seized the frog in mid-air. One of us (MLM) lightly tapped the snake's rostrum with a snake stick and it released the frog, which jumped away without apparent ill effects. The ability to capture a moving airborne prey item provides important information regarding the biomechanical aptitude and foraging behavior of pitvipers. The lack of noticeable venom effects on the frog suggests that some pitvipers might not envenomate some types of prey. Because frogs do not pose a danger to snakes during prey handling, envenomation would not provide any protective benefits to the snake during prey handling, although envenomation might decrease the risk of losing prey.

ALSOPHIS RUFIVENTRIS (Red-bellied Racer). **FORAGING AND DIET**. Despite being widespread in the West Indies, little has been recorded regarding foraging behavior in the colubrid genus *Alsophis*. *Alsophis rufiventris* occurs on Saba and St. Eustatius and has been extirpated on St. Christopher and Nevis. From 3–24 June 2004, we observed four feeding events by *A. rufiventris* on The Quill, a dormant volcano on St. Eustatius. We twice saw snakes eating *Anolis schwartzi*. During one of those encounters, the snake began ingestion before the lizard was completely immobilized. The entire feeding event took ca. 2 min. The second encounter occurred on the rim of The Quill. The snake was on a fallen log about 1 m above the substrate when it struck at something under the leaves of a dead bromeliad. We disturbed the snake by lifting the leaves for a closer look, and the snake fled

with an adult *A. schwartzi* in its mouth. We also saw two instances of snakes eating reptilian eggs (most likely those of *A. schwartzi*). In one instance, a snake was tongue-flicking in leaf litter at a single spot for several minutes, until it grasped and swallowed a small white egg. In the other instance, we disturbed a snake that had been rooting in litter. It dropped a collapsed reptilian egg as it fled.

Field work on St. Eustatius was funded by NSF grant No. DBI-0242589 to R. Powell.

AMPHIESMA STOLATUM (Striped Keelback). **PREY SIZE**. At 0946 h on 16 July 2003, a male *Amphiesma stolatum* (430 mm SVL, 35.66 g) was found ingesting a Spectacled Toad (*Bufo melanosticus*; 55 mm SVL, 14.07 g) on the tiled entrance of the Biological Resource Department building of National Chiayi University, Taiwan (23º28'18"N, 120º29'04"E). The toad was being consumed vent first, and the head and forelimbs were protruding from the snake's mouth. At first the snake tried to flee with the prey item in its mouth. It moved ca. 40 cm and then regurgitated the toad in an attempt to escape.

Published records suggest *A. stolatum* has a broad diet, including insects, amphibians, fish, earthworms, lizards, and scorpions (Das 2002. A Photographic Guide to Snakes and Other Reptiles of India. New Holland Publishers Ltd., London. 19 pp.). Colubrids commonly prey on creatures about 20% of their own mass (Greene 1997. Snakes: The Evolution of Mystery in Nature. University of California Press, Berkeley. 351 pp.), but in this case the prey/predator mass ratio was 39.5%. To our knowledge this is the largest recorded predator/prey mass ratio for this species.

ANILIUS SCYTALE (Red Pipesnake). **CANNIBALISM.** Cannibalism is a common occurrence among reptiles (Polis and Myers 1985. J. Herpetol. 19:99–107). *Anilius scytale*, a South American aniliid, is found in Venezuela, Guyana, French Guiana, and Suriname, and Amazonian portions of Colombia, Ecuador, and Brazil (Cunha and Nascimento 1993. Bol. Mus. Emílio Goeldi 9:1–191). Primarily fossorial and occasionally aquatic and terrestrial when active, it is almost always associated with water bodies (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150). Anecdotal information indicates *A. scytale* feeds primarily on elongate fossorial and aquatic vertebrates (Beebe 1946. Zoologica 31:11–52; Greene 1983. Amer. Zool. 23:432–441), including an observation of feeding on *Atractus torquatus* (Martins and Oliveira, *op. cit.*). A preserved adult male *A. scytale* (MPEG 7243; 430 mm CRC), from the municipality of Capitão Poço (01°44'41"S, 47°03'54"W), Pará, Brazil, contained a conspecific juvenile male (315 mm CRC), ingested head first. The prey represents 74.1% of the predator's total length. This is the first report of cannibalism for *A. scytale*. The low incidence of cannibalism in the *Anilius scytale* (as well as in other species of snakes and lizards) suggests that the predator might not discriminate between conspecifics and other prey items when opportunistically foraging (Pontes et al. 2003. Herpetol. Rev. 34:154).

Fellowships from the Conselho Nacional de Desenvolvimento Científico e Tecnológico and Programa Norte de Pós-Graduação (PNOPG) provided financial support and the Museu Paraense Emílio Goeldi (MPEG) provided logistic support.

ATRACTASPIS IRREGULARIS (Mole Viper or Stiletto Snake). **REPRODUCTION**. *Atractaspis irreglaris* is distributed through east, central, and west Africa (Chippaux 2001. Les Serpents d'Afrique Occidentale et Centrale. Collection Faune et Flore Tropicales 35. Institut de Recherche pour le Développement Editions, Paris. 292 pp.; Spawls et al. 2002. A Field Guide to the Reptiles of East Africa. Academic Press, London. 543 pp.). In east Africa, mating has been observed in September and six eggs were reported in a specimen from Uganda (Spawls et al. 2002, *op. cit.*). In March 2004, we captured a gravid female *A. irregularis* in a garden in Yaoundé, Cameroon (3.5°N, 11.5°E) that subsequently laid three eggs on 8 April 2004. The eggs were measured in the week following oviposition, they had a mean length of 49 mm (SD = 7.8, range = 43–58). The eggs were incubated in a sealed plastic container on moistened dry grass. The temperature in the container ranged from 26.0–29.1°C and the humidity from 61–100%. The eggs hatched sometime between 21 and 29 June 2004. The hatchlings averaged 6.83 g in mass (0.59 SD, range = 6.00–7.25), 209.7 mm SVL (0.39 SD, range = 206–215), and all three had 16 mm long tails.

BOIGA DENDROPHILA (Mangrove Snake). **DIET**. The diet of *Boiga dendrophila* includes a diversity of vertebrates, including lizards, snakes, birds, and mammals (Greene 1990. Proc. California Acad. Sci. 46:193–207). Herein I report a novel species and order (Scandentia) in the diet of *B. dendrophila*. While radio-tracking a Large Treeshrew (*Tupaia tana*; 190–240 g) on the morning of 18 September 2003 at the Danum Valley Field Center in northeast Borneo (4°58'N, 117°48'E), I found a large *B. dendrophila* coiled around a tree branch ca. 5 m off the ground. I determined that the radio signal of the *T. tana* was emanating from the general location of the *B. dendrophila*, which was noticeably distended at mid-body. Neither the snake nor the radio signal moved the rest of that day. The next day the snake had moved ca. 100 m and was found by tracking the radio signal. After a third day, neither the signal nor the snake could be located despite a thorough search. *Tupaia tana* is one of the most numerous diurnal mammals in lowland Bornean rainforests (45–55 individuals/ km^2; Emmons 2000. Tupai: A Field Study of Bornean Treeshrews. Univ. California Press, Berkeley. 269 pp.) and might represent a significant component of the diet of *B. dendrophila* on Borneo. I thank H. W. Greene for reviewing this manuscript.

BOIGA KRAEPELINI (Taiwanese Tree Snake). **DIET**. *Boiga kraepelini* is the only member of this genus that naturally occurs in Taiwan, where it inhabits low to medium elevation habitats island-wide. At 0800 h on 28 March 2003 an adult female *B. kraepelini* (1318 mm TL) was found dead on the side of a road next to an electrical pole, near the main entrance of the Taitung Animal Propagation Station (22°49'08"N, 121°04'58"E, elev. 132 m). Upon dissection we found a 32.7 g dove chick in the specimen's stomach. The chick is probably either a Red Turtle Dove (*Streptopelia tranquebarica*) or a Spotted Dove (*Streptopelia chinensis*), both of which are very common in this area. *Boiga kraepelini* is known to prey on a variety of vertebrates, including birds, lizards, and mice (The Transition World - Guidebook of Amphibians and Reptiles of Taiwan. SWAN, Taipei, pp. 176–177). To the best of our knowledge, this is the first report of predation by *B. kraepelini* on a dove chick.

Submitted by **HSIEN-PIN CHU,** Taitung Animal Propagation Station No. 30, Community 27, Binlang Village, Beinan, Taitung County, Taiwan 954, Republic of China; **GERRUT NORVAL,** Applied Behavioural Ecology & Ecosystem Research Unit, Department of Nature Conservation, UNISA, Private Bag X6, Florida, 1710, Republic of South Africa (e-mail: gerrutnorval507@yahoo.com); and **JEAN-JAY MAO,** Department of Natural Resources, National I-Lan University, No. 1, Shen-Non Rd., Sec. 1, I-Lan City 260, Taiwan, Republic of China.

BOTHRIECHIS SCHLEGELII (Eyelash Palm Pit-viper, Bocaracá). **ATTEMPTED PREDATION**. *Herpetotheres cachinnans* (Laughing Falcon) is a common resident of lowland forest on both the Caribbean and Pacific slopes (up to 1850 m elevation) of Costa Rica (Stiles and Skutch 1989. A Guide to the Birds of Costa Rica. Cornell University Press, Ithaca, New York. 511 pp.). *Herpetotheres cachinnans* is known for its almost exclusive diet of snakes, including a "coral snake or a mimic thereof," vine snakes (*Oxybelis*), micas (*Spilotes pullatus*), and a "slender, green, arboreal snake" (Skutch 1983. *In* Janzen [ed.], Costa Rican Natural History, pp. 593–594. University of Chicago Press, Chicago, Illinois; Skutch 1999. Trogons, Laughing Falcons, and Other Neotropical Birds. Texas A&M University Press, College Station, Texas. 222 pp.). To my knowledge there have been no reports of pitvipers in the diet of laughing falcons. At 1515 h on 18 February 1999, I observed a *H. cachinnans* with a *Bothriechis schlegelii* at Parque Nacional Carara (09°46'27.0"N, 84°36'20.0"W). The adult *H. cachinnans* dropped the adult male *B. schlegelii* from a branch ca. 3 m above the ground. The snake's spine was severed and it lay motionless. The *H. cachinnans* remained perched over the snake with out moving until dusk (ca. 1730 h), when it flew off without the snake.

The *B. schlegelii* was deposited in the Texas Cooperative Wildlife Collections at Texas A&M University (TCWC 83394). I thank John H. Malone and Lee Fitzgerald for reviewing a draft of the manuscript. The inventory was conducted under MINAE RESOLUCION N°. 237-98-OFAU.

Submitted by **DAVID LAURENCIO**, Department of Wildlife and Fisheries Sciences, 215 Old Heep, MS 2258, Texas A&M University, College Station, Texas 77843-2258, USA; e-mail: norops@tamu.edu.

BOTHROPS ERYTHROMELAS (Caatinga Lancehead). **REPRODUCTION**. *Bothrops erythromelas* inhabits xeric and semi-arid regions in northeastern Brazil under clusters of bromeliad, *Bromelia laciniosa* (Amaral 1923. Proc. New England Zool. Club 8:96–97) and riparian forests (Vanzolini et al. 1980. Répteis das Caatingas. Acad. Bras. Ciênc. Rio de Janeiro. 161 pp.). Lira-da-Silva et al. (1994. Revista Brasileira de Zoologia 11:187–193) collected a gravid female in the wild from Paulo Afonso, Bahia, Brazil. On 11 Jan 1993 (after ca. 123 days of gestation), this snake gave birth in captivity to 11 neonates (mean SVL = 192 mm ± 2.5 SD, range = 168–192). Machado and Cotta (1998. XXII Congresso Brasileiro de Zoologia, Abstract 1118.) reported that eight male and eight female *B. erythromelas* mated in captivity April–May 1991, with six females giving birth (mean = 11.4 neonates) in December and January after ca. 240 days of gestation. Here we report data on two litters of *B. erythromelas* born in captivity on 20 November 1998 and 11 November 2002, both from females collected in the wild. The first female was collected in March 1998 from Maracás, Bahia, Brazil (13°44'S, 40°43'W; 964 m) and gave birth after ca. 257 days of gestation to six live female neonates (IB 60518–60523; mean SVL = 184 mm ± 48 SD, range = 179–190; mean mass = 4.17 g ± 1.17 SD, range = 3.0–6.0 g). The second gravid female (590 mm SVL, 174 g) was collected in October 2002 from Brumado, Bahia, Brazil (14°20'S; 41°66'W, 422 m elev.) and gave birth after 32 days in captivity to two male and four female live offspring (mean SVL = 196 mm ± 5 SD, range = 190–205).

BOULENGERINA ANNULATA STORMSI (Storm's Water Cobra). **ATTEMPTED PREDATION**. *Boulengerina annulata* is a stout-bodied piscivorous cobra found in and near the waters of the Congo Basin (Spawls et al. 2002. A Field Guide to the Reptiles of East Africa. Academic Press, London, England. 543 pp.). *Boulengerina a. stormsi* is restricted to Lake Tanganyika.

On the morning of 17 June 2003, we found a recently-killed adult female *B. a. stormsi* (1175 mm SVL; 1440 mm TL) floating a few meters from the Kasaba Lodge jetty (08°35'N, 30°30'E), Kasaba Bay, Lake Tanganyika, Zambia. There were a total of 16 punctures clustered in four main areas of trauma, two of which completely severed the spine. The first trauma area was 37–64 mm posterior of the snout, and featured a 9 mm entry wound at the rear of the head. The spine was severed, the palate punctured, and there was an apparent exit wound through the lower jaw. Another puncture wound was 27 mm posterior to the primary wound at the edge of the ventral scales. The second trauma area was 207–248 mm posterior of the snout, and included a 10 mm diameter puncture that severed the spine and exited the right body wall. Two superficial wounds were 37 and 41 mm behind the primary wound. The third trauma area was 351–378 mm posterior of the snout and included a 5 mm puncture on the right dorsum (anterior) and a superficial wound on the lower left side (posterior). The fourth trauma area was 511 mm posterior of the snout and consisted of an 11 mm axial gash on the left dorsal surface that exited the body wall on the lower right side.

These injuries are inconsistent with the most obvious threats to *B. a. stormsi* in Kasaba Bay: contact with an outboard engine, inadvertent entanglement in a fisherman's gill net, deliberate human persecution, or attack by Nile Crocodile (*Crocodylus niloticus*), Clawless Otter (*Aonyx capensis*), or Hippo (*Hippopotamus amphibius*). We believe the wounds are the result of attempted predation by a bird-of-prey. The arrangement of the punctures in four groups along the anterior half of the body, the specific damage to the head, and the complete penetration of the spine and body in several places are consistent with attack by a raptor. The African Fish Eagle (*Haliaeetus vocifer*) was the only large raptor observed during our visit; we saw five individuals along the shoreline opposite the lodge. Fish Eagles usually take live and dead fish from the water surface, but have also taken juvenile Nile Crocodiles (*Crocodylus niloticus*) and Serrated Terrapins (*Pelusios sinuatus*; Broadley 1974. Honeyguide 78:11–19). They have also been observed capturing a swimming Green Snake (*Philothamnus* sp.; Sweeney 1971. Snakes of Nyasaland. A. Asher & Co., Amsterdam. 200 pp.) and stealing an unidentified snake from a Martial Eagle (*Polemaetus bellicosus*; van Vuuren 1984. African Wildlife 38:30). Snouted Cobras (*Naja annulifera*) and Mozambique Spitting Cobras (*Naja mossambica*) have been consumed by various other African raptors (Broadley 1959. Bull. Mus. Comp. Zool. 120:1–100; Lendrum 1979. Ostrich 50:203–214; Steyn 1973. Ostrich 44:1–22; Steyn 1980. Ostrich 51:54–55; Sweeney 1961, *op. cit.*). Water cobras are routinely exposed to aerial predators when surfacing to breath. It is possible that the apparent pre-ecdysis condition of the cobra, indicated by opaque eyes, may have made it less alert and more vulnerable to aerial predation. Though the damage inflicted in this case was clearly sufficient to kill the cobra, there was no evidence of feeding on the corpse. The specimen was preserved in ethanol and left with Kalambo Lodge, Zambia. We thank Toby Veall, Tabatha Bruce, Don Broadley, and Harry Greene for assistance and thank YAP Films and Animal Planet for funding "O'Shea's Big Adventure Series 4: Water Cobra."

CHARINA BOTTAE (Rubber Boa). **RELATIVE PREY MASS.** *Charina bottae* is known to feed primarily on small mammals (especially their young), occasionally larger mammals (e.g., chipmunks, nestling rabbits), and squamate reptiles and their eggs (Rodriguez-Robles et al. 1999 J. Zool. London 248:49–58; St. John 2002. Reptiles of the Northwest. Lone Pine Publ. Renton, Washington. 272 pp.). Rodriguez-Robles et al. (1999, *op. cit.*) reported a predator-prey mass ratio of 0.65 for an adult *C. bottae* that had ingested six nestling Deer Mice (*Peromyscus maniculatus*). Here, I report an estimated predator-prey mass ratio for *C. bottae* more than double of that previously reported.

On 17 July 2004, at 0310 h I captured a female *C. bottae* (235 mm SVL, 6.3 g) on the Vantage Highway, 29.8 km E of Ellensburg, Kittitas County, Washington, USA. Manual palpation of this specimen indicated six distinct prey items. The most anterior prey item was palpated out of the stomach and identified as a nestling murid rodent (most likely a Sagebrush Vole, *Lagurus curtatus*). The mass of this nestling was 1.54 g. The contours (the body and head of each nestling could be felt) of the remaining five prey items indicated that they were as intact as the nestling palpated from the stomach. Assuming that the remaining five prey were conspecific nestlings, each with a mass equivalent to that of the first, the total mass of ingested prey would equal 9.24 g for a predator-prey mass ratio of 1.46. A value such as this is on par with some of the highest recorded for any snake species (e.g., 1.57 for *Bitis caudalis*, Branch et al. 2002. Herpetol. Rev. 33:137–138; 1.72 for *Crotalus cerastes*, Mulcahy et al. 2003. Herpetol. Rev. 34:64). Such feats of ingestion typically involve a single large prey item, usually much larger in diameter than the head of the snake consuming the meal. In this case, the ingestion ratio (width of prey item/width of the snakes head) was much lower than if it were to consume a single larger prey item.

I thank D. Darda, M. Lahti, P. Mattocks, R. Hoyer, and A. St. John for assistance.

CHARINA BOTTAE (Rubber Boa). **DIET**. *Charina bottae* feed primarily on mammals, although lizards, birds, and squamate eggs

are sometimes taken (Rodríguez-Robles et al. 1999. J. Zool., Lond. 248:49–58). Rubber Boas have been reported to raid rodent nests and consume multiple individuals during a single feeding event (Rodríguez-Robles et al. 1999. J. Zool. 248:49–58). Their blunt tails often show evidence of injury (Hoyer 1974. Herpetologica 30:275–283) and may serve to misdirect attacks by predators (Greene 1973. J. Herpetol. 7:143–161) or protective mother rodents (Hoyer and Stewart 2000. J. Herpetol. 34:354–360).

On 10 July 2004 we collected an adult male *C. bottae* (457 mm SVK, 64 mm TL, 61.4 g) from inside a fallen Lodgepole Pine (*Pinus contorta*) at the edge of an open meadow in mixed coniferous forest at Sagehen Creek Field Station, Nevada County, California (39.43228°N, 120.24150°W, 2014 m elev.). The boa voluntarily regurgitated two adult Montane Voles (*Microtus montanus*) shortly after capture. The combined mass of the prey was 38.4 g, a relative prey mass (prey mass/predator mass) of 0.63. To the best of our knowledge, this is the first verified report of *C. bottae* predation on *M. montanus*, although Fitch (1936. Am. Midl. Nat. 41:513–579) mentions a possible record. The voles and boa are deposited in the Museum of Vertebrate Zoology (MVZ 245392).

We thank J. Patton and E. Lacey for assistance.

CHRYSOPELEA ORNATA, C. PARADISI (Flying Snakes). **BEHAVIOR**. Animals subject to airborne predation are known to react defensively to stimuli moving overhead. For example, Tinbergen (1948. Wilson Bull. 60:6–51) demonstrated that raptor-like silhouettes elicit defensive responses in gallinaceous birds. However, relatively few studies have examined such behavior in reptiles (Macias Garcia and Drummond 1995. Ethology 101:101–111; Fine 1999. J. Herpetol. 33:128–131). Here we report orienting responses of *Chrysopelea ornata* and *C. paradisi* to visual stimuli of overhead flyers. These observations were made during experiments designed to evaluate takeoff and gliding performance of these species in semi-natural conditions (Socha 2002. Ph.D. Thesis, Univ. Chicago).

On separate occasions, we observed two *C. ornata* specimens visually track airplanes that flew overhead in the course of an aerial performance study in Lockport, Illinois. A branch (1 m long) was affixed horizontally to a scaffolding tower at a height of 8.3 m in the middle of an open, grassy field. In a typical flight trial, the snake was placed at the proximal end of the branch with its head facing outward; most snakes immediately moved to the distal end of the branch and jumped. In one trial, the snake (92 cm SVL, 158 g) moved to the end of the branch and stopped. While resting, the snake made a sudden move with its head, shifting its anterior body (ca. 8 cm) upward from horizontal to the vertical and twisting to the right, as if pointing up into the sky. We looked in the same direction and determined that the snake was directly facing an orange and tan Southwest Airlines passenger jet (casting a ca. 3 cm silhouette) as it moved slowly across the sky. The snake tracked the plane in saccadic fashion as it crossed from right to left, making three separate twisting movements. At the time of our initial sighting, we could not hear the airplane. Once the plane disappeared from view, the snake returned to its original posture. Several weeks later, JS observed identical plane-watching behavior in a second *C. ornata* (89 cm SVL, 150 g) and photographed the snake's posture (Fig. 1). The total duration of this behavior was ca. 30 s.

While conducting experiments at the Singapore Zoological Gardens, JS observed one instance of a similar visual orienting

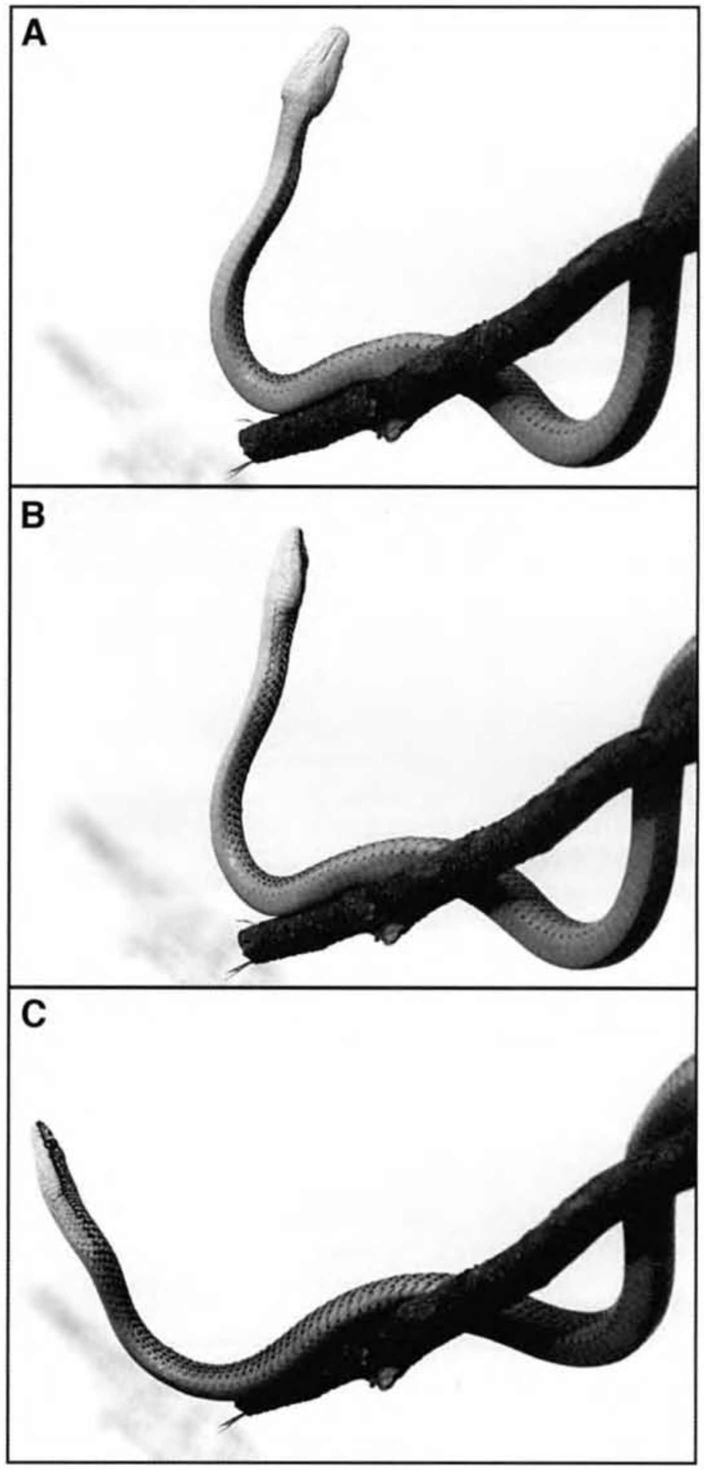

FIG. 1. *Chrysopelea ornata* visually tracking an airplane as it passed overhead through the sky. Temporal sequence is from top to bottom.

behavior in *C. paradisi*. This time, the stimulus was an unidentified bird (wingspan ca. 1 m) and the snake (85 cm SVL, 83 g) was facing to the left with ca. 15 cm of the anterior end in the air and the remainder of the body perched along the branch. The bird flew overhead, passing from the left to right at an estimated height of 100 m. The snake first reacted to the bird at a distance of ca. 200 m by turning its head 20° to the right and upward at an angle of 45°. The snake tracked the bird in saccadic fashion, making four discrete movements and rotating through a total angle of ca. 90° over 13 s. During this behavior, the snake moved its head from side-to-side intermittently with an amplitude of a few mm. After the bird was out of view, the snake returned to a forward-facing position.

Vision was presumably responsible for the initial detection of the overhead flyers in these observations. The first plane spotted by a *C. ornata* specimen was relatively small, and although the ophidian auditory system is more sophisticated than popularly believed (Young 2003. J. Comp. Physiol. B 167:481–493), it seems improbable that the snake was alerted by a sound that we could not hear (at any frequency, the threshold of audibility is lower in humans than in snakes; Hartmann 1997. Signals, Sound, and Sensation, American Institute of Physics, Woodbury, New York; Young 2003, *op. cit.*). Furthermore, the bird detected by the *C. paradisi* specimen appeared to make no sound.

Although our behavioral observations were made in semi-natural conditions, these data suggest two broad predictions regarding *Chrysopelea*. First, birds are important predators of flying snakes in the wild; this prediction can be tested through natural observations or dietary studies. Furthermore, possible links between detection of predators and initiation of takeoff may lend insight into the conditions under which aerial locomotion in snakes evolved. Second, we predict that flying snakes have excellent vision relative to most non-flying snakes, which can be tested by examining the distribution of morphological characters associated with keen visual acuity across a phylogenetically appropriate sample of snake taxa. Although snakes are generally thought to have poor vision, some taxa (e.g., *Ahaetulla* spp., Walls 1942. Bull. Cranbrook Inst. Sci. 19:1–785) possess foveae, which function to increase visual acuity in a diversity of animals (Ross 2003. *In* Anthropoid Origins: New Visions, pp. 463–521. Kluwer Academic/ Plenum Publishers, New York). We predict that *Chrysopelea* spp., with their unique command of aerial navigation and possible pre-takeoff target selection (Socha 2002, *op. cit.*) have functional foveae.

CROTALUS ATROX (Western Diamondback Rattlesnake). **PREDATION.** At ca. 1000 h on 20 March 2004, we observed from a distance of ca. 60 m a Bobcat (*Lynx rufus*) with a rattlesnake on San Bernardino National Wildlife Refuge, Cochise Co., Arizona. The *L. rufus* swiped and bit at the snake, and eventually grabbed and tore a piece of flesh from it. The snake then struck at the *L. rufus*, which jumped several feet into the air. The *L. rufus* subdued the snake, picked up its prey, and walked in front of the parked vehicle at a distance of ca. 10 m (Fig. 1). At this time the snake was identified as *Crotalus atrox*, and appeared to exceed 100 cm TL. The *L. rufus* proceeded to a riparian area, where it disappeared.

At 2330 h on 13 August 2004, we observed a *L. rufus* carrying a dead *C. atrox* crossing New Mexico Highway 61 at 38.1 km N and 12.2 km W of Deming, New Mexico. The *L. rufus* dropped the snake on the pavement and then slowly wandered off in a disoriented manner. It zigzagged and held its head down, suggesting it had been struck one or more times. The body of the *C. atrox* (MSB 71139; 970 mm SVL, 605 g) had numerous puncture wounds, primarily over the posterior 2/3 of the body. Many tail punctures were evident and the rattle string appeared to have been ripped off during the encounter with the *L. rufus*.

Shaw and Campbell (1974. Snakes of the American West. Alfred A. Knopf, Inc., New York 330 pp.) mention, "Coyotes, foxes, wildcats, and badgers all will eat rattlesnakes." Klauber (1997. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. University of California Press, Berkeley. 1580 pp.) describes a *L. rufus* consuming a dead *Crotalus mitchelli* (Speckled Rattlesnake). To the best of our knowledge, there are no accounts of *L. rufus* taking live *Crotalus*, and *Crotalus* are not listed as prey items for *L. rufus* in the mammalian literature (Lariviere and Walton 1997. Mammalian Species 563:1–8). We thank C. Painter for advice and assistance.

CROTALUS HORRIDUS (Timber Rattlesnake). **REPRODUCTION.** In many snakes, including rattlesnakes, female ecdysis and male-male fighting are associated with the reproductive cycle (Aldridge and Duvall 2002. Herpetol. Monogr. 16:1–25; Duvall et al. 1992. *In* Biology of the Pitvipers, pp. 321–335 [and citations therein], Selva Press, Tyler, Texas). Here we report female ecdysis, courtship, male-male combat, and copulation among three *Crotalus horridus*, all within a few hours.

On 4 August 2001 at 1245 h, we encountered a male *C. horridus* (M1; ca. 1150 mm TL) courting a female conspecific (ca. 900 mm TL) on a forested talus slope adjacent to a *C. horridus* den in northeastern New York. The female had begun shedding, and most of the skin on her head had already been sloughed. After ca. 20 minutes, the male effected cloacal apposition, although we do not believe the pair was copulating at that time. Approximately 65 minutes later, a second male (M2; ca. 1000 mm TL) steadily and directly ascended the slope and approached the courting pair. The two males began fighting immediately upon contact. The males repeatedly rose and fell, proceeding progressively further down the slope and eventually out of view (15–20 m). Meanwhile, the female crawled under nearby rocks and completed shedding. Approximately 15 min later, M1 returned upslope alone, searched for the female for several minutes, and upon finding her resumed courtship. Twenty minutes later, M2 returned upslope, eventually re-encountering the courting pair. The courting male (M1) left the female and approached M2, resulting in M2's rapid retreat down the slope. M1 followed for several meters, with no contact between them. The female then moved upslope, toward the den. M1 and M2 continued searching for the female for about 20 min, whereupon we briefly departed. Upon our return, ca. 15 min later, we found M1 again courting the female, and ca. 20 min later observed intromission. Another 20 min later, M2 returned upslope, encountered the copulating pair, and began courting the female. M1 did not appear to react. The female moved slowly upslope while M1 attempted to stay in place. We terminated observations ca. 30 min later at 1630 h. At this time, M1 and the female were still copulating and M2 continued courtship behaviors.

Our observations are consistent with evidence that both female ecdysis and male fighting are associated with the mating season in rattlesnakes (Aldridge and Duvall, *op. cit.*; Duvall et al., *op. cit.*; and citations therein). Although some studies suggest that defeated male pitvipers are less likely to re-engage in combat or attempt to court females (Schuett 1997. Anim. Behav. 54:213–224), in this case, a seemingly defeated (and smaller) male repeatedly returned to the vicinity of a dominant male to pursue and court a female.

We thank W. S. Brown, E. McGowan, B. Coupe, R. Stechert, K. B. Merrow, and L. Aubertin for guidance and/or assistance.

CROTALUS SCUTULATUS (Mohave Rattlesnake). **BEHAVIOR**. Klauber (1956. Rattlesnakes, Their Habits, Life Histories, and Influence on Mankind. Univ. California Press, Berkeley, California. 1476 pp.) cites several reports of rattlesnakes occupying prairie dog (*Cynomys* sp.) towns in the general vicinity of Prairie Dogs and, in some cases, Burrowing Owls (*Athene cunicularia*). However, Klauber (1956, *op. cit.*) describes reports of animals (besides other snakes, but specifically mentioning Burrowing Owls) hibernating with rattlesnakes as "fortuitous," adding, "it is to be doubted whether these go beyond the other animals' accidentally selecting an adjacent refuge."

On 11 November 2003, I located a radio-tagged male *C. s. scutulatus* (826 mm SVL) in an abandoned Kit Fox (*Vulpes macrotis*) burrow in the western Mojave Desert in San Bernardino County, California, USA (34.50°N, 117.25°W). The burrow consisted of seven entrances occupying an area of 4.5 m x 6.0 m. Each burrow entrance angled down and generally toward the center of the group of openings. The snake's presence in the burrow was verified electronically on 15 occasions during the following four months, although he was never visually observed over the winter. On thirteen of those occasions, a single *A. cunicularia* was observed at the burrow (either standing at one of the burrow entrances, peeking over the soil mound at an entrance, or taking flight). During this period, numerous fresh avian scats and regurgitated owl pellets accumulated around the burrow entrances. Throughout the winter, the snake's strongest radio signal emanated from near the center of the group of burrow entrances and presumably corresponded to his underground location. Although it is clear that at least one owl occupied the burrow continuously between 11 November 2003 and 29 February 2004, its underground proximity to the rattlesnake could not be determined. However, based on the burrow entrances utilized by the owl, the location of the snake's strongest radio signal, and the converging angles of the entrances, it is estimated that they spent much of the winter within 3 m of each other. On 13 March 2004, I located the snake on the surface ca. 15 m from the burrow; the owl was not observed at the burrow on this day, but a White-tailed Antelope Ground Squirrel (*Ammospermophilus leucurus*) was observed moving among the burrow openings.

CROTALUS SIMUS TZABCAN (Neotropical Rattlesnake). **DIET**. Although *Crotalus simus tzabcan* is known to consume a variety of rodents, lizards, and birds (Lee 1996. The Amphibians and Reptiles of the Yucatán Peninsula. Cornell University Press, Ithaca, New York, 500 pp.; Campbell 1998. Amphibians and Reptiles of Northern Guatemala, the Yucatán, and Belize. University of Oklahoma Press, Norman, Oklahoma, 400 pp.), relatively few specifically identified prey have been reported. On 13 November 2003 at 0900 h we found a juvenile *C. s. tzabcan* (525 mm SVL, 87 g) dead on the road near Chetumal City, Quintana Roo, México (18°32'45"N, 88°16'04"W). The snake contained a

subadult male House Mouse (*Mus musculus*) that it had swallowed headfirst. The mouse measured 81 mm total length and weighed 15.3 g. Both the *C. s. tzabcan* (ECO-CH-H 2192) and the *M. musculus* (ECO-CH-M 2127) are deposited in El Colegio de la Frontera Sur, Chetumal, Quintana Roo, México. We thank E. Escobedo for identifying the mouse.

DRYMARCHON CORAIS (Indigo Snake). **DIET.** *Drymarchon corais*, the longest North American snake, is known to consume a variety of prey items, including frogs, rodents, and other snakes, including venomous ones (Belson 2000. Herpetol. Rev. 31:105; Moler 1992. Rare and Endangered Biota of Florida. Vol. 3. Amphibians and Reptiles. University Press of Florida, Gainesville, Florida. 291 pp; Wright and Wright 1957. Handbook of Snakes of the United States and Canada, Vol. 1. Comstock Publishing Associates, Ithaca, New York. 564 pp.). Here we report two novel foraging observations for *D. corais*.

On 25 October 1996 while conducting a bird survey in Tamaulipan Thorn Scrub at the Ejido Vistahermosa (25°45'45"N, 99°35'05"W; 400 m elev.), in the municipality of Linares, Nuevo León, México, we found an Olive Sparrow (*Arremonops rufivirgatus*), a Golden-fronted Woodpecker (*Melanerpes aurifrons*), and a Common Ground-dove (*Columbina passerina*) entangled in our mist net. An adult *D. corais* (155 cm TL) was found consuming the *A. rufivirgatus* and part of the net at 1103 h. The snake was also tangled within the net, and we separated it from the net and released it.

On 23 June 2003 while conducting a herpetological survey in a Matorral Submontane biotic community in the municipality El Carmen (26°43'25"N, 101°21'45"W; 489 m elev.), Nuevo Leon, México, we found an adult male *D. corais* (150 cm TL). While held in a collecting bag, this specimen regurgitated five young *Gopherus berlandieri* (4.2, 3.6, 3.3, 3.2, and 3.1 cm plastron length). Two of the tortoises were still partially encased by egg membrane. The tortoises were preserved (deposited at UANL-FCB- Laboratorio Herpetologia) and the snake was released.

ELAPHE ALLEGHANIENSIS (Eastern Ratsnake). **FORAGING BEHAVIOR.** Egg-eating is well known in ratsnakes, although aspects of the behavior vary. The basic method is for the snake to position the egg for swallowing, work the jaws over the egg to get it into the mouth and anterior neck, and use the lateral neck muscles to push it down into the stomach. Ratsnakes are known to swallow eggs entirely and digest the shells and contents in the stomach (Brimley 1941–1942. Carolina Tips 4–5:19–26; Gibbons 1999. Waterfowl Mag. 17[4]:23–24, 38–39). They are also known to break the egg inside the esophagus, swallow the contents, and regurgitate or swallow the empty shell (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Inst. Press, Washington, DC. 668 pp.; Werler and Dixon 2000. Texas Snakes, Identification, Distribution, and Natural History. Univ. Texas Press, Austin, Texas. 437 pp.). Eggs may be broken using constriction of neck muscles or by pushing them against the hypapophyses of the cervical vertebrae (Mullin 1996. Amphibia-Reptilia 17:387–394). We describe egg eating in the Eastern Ratsnake in which the egg is broken by behavioral action.

At ca. 1300 h on 23 May 2002 an adult *E. alleghaniensis* was observed entering a chicken coop in Greene County, Virginia (UTM 17S 0719511, 4246647, NAD 83). The surrounding habitat is mixed hardwood/pine forest. After the snake entered the chicken coop, it immediately entered a large wooden nest box and consumed several eggs before video and still cameras were procured to record the consumption of others. The following description is based on these recordings. The snake located each egg in the box via tongue flicking and once found, prodded the egg with its snout. On two attempts, the snake opened its jaws to grab one of the "ends" of the egg, but one egg was grabbed in the middle and then "jaw walked" until one of the ends was located. Through a combination of pushing against the egg (still in contact with the substrate) and alternating movements of the jaws, the egg was worked toward the back of the mouth. Once the lower mandibles were completely around the egg and it was no longer in contact with the substrate, the head and ca. 7–10 cm of the neck were lifted so that they were nearly perpendicular with the ground. At this point the egg was positioned posterior to the teeth but anterior to the muscles in the throat. It appeared that by lifting the egg, the snake was using gravity to aid in passing the egg beyond this critical point. Once the egg moved further into the throat, the snake lowered its head and neck region back into contact with the ground. A series of muscle contractions moved the egg into the throat ca. 10 cm posterior to the jaws. The snake then created a sharp bend in its neck just anterior to the egg and raised ca. 5 cm of its body off the ground just posterior to the egg. With an abrupt, rapid, forward movement, the snake pushed the section of its neck anterior to the egg downward against the substrate in an effort to break the egg. The section of the neck holding the egg maintained contact with the substrate during this entire motion. The snake appeared to break the eggs via concentrated downward pressure against the substrate. The bend in the neck just anterior to the egg presumably prevented the egg from moving back into the oral cavity during the application of this pressure. There was a distinct cracking or popping sound when the egg broke. The snake cracked eggs in one motion when on a hard surface (wood floor), but had to make several attempts when on softer material (wood chips). Once the egg was broken the shell and contents were moved to the stomach through a series of muscle contractions. This same snake (identified by a scar) was found in the chicken coop with a

distended stomach again on 19 June 2002. Cracked eggshells were easily palped in the stomach. Whether this mode of breaking eggs is learned or innate is unknown. It does demonstrate that ratsnakes use several means to break avian eggs during consumption.

Submitted by **WILLIAM BROWN**, Blue Ridge Biological, 978 Bull Yearling Road, Stanardsville, Virginia 22973, USA (e-mail: wbrown@blueridgebiological.com); and **JOSEPH C. MITCHELL**, Department of Biology, University of Richmond, Richmond, Virginia 23173, USA.

ELAPHE ALLEGANIENSIS (Eastern Ratsnake). **DIET**. Ratsnakes are well known predators of birds and their eggs (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Inst. Press, Washington, DC. 668 pp.; Wright and Wright 1957. Handbook of Snakes of the United States and Canada. Cornell Univ. Press, Ithaca, New York. 1005 pp.). Ratsnakes consume a variety of large avian prey, including fledgling ducks, wading birds, and large woodpeckers. Western Ratsnakes (*Elaphe obsoleta*) have successfully preyed upon fledgling Pileated Woodpeckers (*Dryocopus pileatus*; Moore 1984. Bull. Oklahoma Ornithol. Soc. 17:32–33). Central Ratsnakes (*E. spiloides*) have unsuccessfully attempted to prey on *D. pileatus* (Noland 1960. Kentucky Warbler 36:29–30), perhaps because of the behavior of the male parent which is known to kill large ratsnakes (Nolan 1959. Wilson Bull. 71:381–382). An Eastern Ratsnake (*E. alleganiensis*) attempted predation on a fledgling *D. pileatus* in Pennsylvania (Hoyt 1957. Ecology 38:246–256), but the bird was removed from the snake's mouth before it could be swallowed. *Elaphe alleganiensis* have also been reported to spend up to five days in *D. pileatus* nest cavities without taking the nestlings (Kilham 1959. Wilson Bull. 71:191). Thus, unambiguous records of *E. alleganiensis* predation on *D. pileatus* are lacking. Here I report a confirmed instance of *E. alleganiensis* predation on *D. pileatus*, the largest extant woodpecker in the range of this snake.

On 17 June 1997, C. T. Georgel and I found a dead adult male *E. alleganiensis* with a large lump in its body on the ground in a training area on Fort Belvoir (U.S. Army), Fairfax County, Virginia (38°41'17.5"N, 77°10'49.8"W). Humans had apparently killed the snake, as the head, neck, and tail had been severed and presumably discarded. When entire, I estimate the snake measured 180 cm TL. Field dissection revealed a large (ca. 25 cm from tip of the beak to the distal end of the pygostyle; 200 g), late-stage fledging *D. pileatus* in its stomach that had been swallowed headfirst. Both the snake and woodpecker were in advanced stages of decomposition.

Submitted by **JOSEPH C. MITCHELL**, Department of Biology, University of Richmond, Richmond, Virginia 23173, USA; e-mail: jmitchel@richmond.edu.

ELAPHE GUTTATA GUTTATA (Red Rat Snake). **DEFENSIVE BEHAVIOR**. Body posture and body motion, such as flattening, tail rattling, and head bobbing, are important aspects of the behavioral repertoire of many reptilian species. Here we report a previously undescribed behavior in *E. guttata*. One of us (JUV) captured a 795 mm SVL (927 mm TL) female *E. guttata* at the western terminus of Malabar Road, Brevard County, Florida, USA. The snake was briefly restrained by hand, with the anterior two thirds of its body, including its head, free and off the ground. In this position, the snake engaged in repeated bouts of defensive behavior each characterized by vertical head bobbing followed by a defensive strike. Between strikes, the suspended snake maintained an S-shaped coil posture. A second juvenile *E. guttata* captured on FH 13 bordering the north edge of the Bradwell Bay Wilderness in Wakulla County, Florida displayed similar head-bobbing behavior, while on the ground (unrestrained) and without exhibiting other characteristically defensive behaviors (i.e., strikes, tail vibration, body-bridging, S-coil, etc). In the popular literature, head bobbing, head jerking, or head twitching behavior has been described in a number of distantly related species including *Lampropeltis calligaster*, *Crotalus cerastes*, and *Sistrurus miliarius* (see Ernst and Ernst 2003. Snakes of the United States and Canada, Smithsonian, Washington). Head bobbing and/or head shaking is a well-known mechanism for visual communication of information between conspecific lizards (*cf.* Carpenter 1961. Copeia 1961:396–405 [*Dipsosaurus dorsalis*]; Carter 1990. Mem. Queensland Mus. 29:333–338 [*Varanus varius*]; Echelle et al. 1971. Herpetologica 27:271–288 [*Anolis* sp.]) and tortoises (Auffenberg 1965. Copeia 1965:335–342). In snakes, however, such behavior is little known, and its adaptive significance is unclear. The fact that the behaviors reported here occurred during encounters with potential predators suggests that this response represents either a displacement activity (an apparently irrelevant act appearing during motivational conflict) or some form of anti-predator mechanism.

Submitted by **JAMES U. VAN DYKE** and **MICHAEL S. GRACE**, Department of Biological Sciences, Florida Institute of Technology, 150 West University Boulevard, Melbourne, Florida 32901, USA; e-mail (MSG): mgrace@fit.edu.

ELAPHE OBSOLETA (Texas Ratsnake). **DIET**. Although it is well documented that *Elaphe obsoleta* commonly consume avian prey, juveniles are known to prey on small mammals, amphibians, lizards and their eggs, but not birds (Ernst and Ernst 2003. The Snakes of North America. Smithsonian Books, Washington and London. 668 pp; Werler and Dixon 2000. Texas Snakes. University of Texas Press, Austin, Texas. 437 pp.). We collected a juvenile female *E. obsoleta* (16.7 g, 360 mm SVL) on 20 April 2003 from a wooden nest box that had contained six Carolina Chickadee (*Poecile carolinensis*) nestlings. The snake had eaten one of the nestlings, which was subsequently weighed (5.2 g) and preserved in formalin. Ingestion ratio and weight ratio (Greene 1983. Amer. Zool. 23:431–441) were 1.25 and 0.311, respectively.The snake and its prey were deposited at the University of Texas at Arlington (UTA R-52380). This specimen was also reported as a county record by Braman and Fontenot (2003. Herpetol. Rev. 34:388). On 4 May 2003, another juvenile *E. obsoleta* was removed from a nest box (from which Carolina Chickadee nestlings had recently fledged) a few hundred yards from where the first was caught.

Submitted by **SHELBY C. BRAMAN** and **PAUL M. HAMPTON**, Department of Biology, University of Texas at Tyler, 3900 University Boulevard, Tyler, Texas 75799, USA (e-mail: shelbybraman@hotmail.com).

EPICRATES INORNATUS (Puerto Rican Boa). **CANNIBALISM.** Cannibalism is rare not only in snakes, but in reptiles in general (Polis and Myers 1985. J. Herpetol. 19:99–107; Pough et al. 2001. Herpetology. Prentice Hall, Upper Saddle River, New Jersey, 612 pp.). Here, we document cannibalism in *Epicrates inornatus*, a medium-sized boa that frequents forest floors, trees, and vines at the entrance of caves. Its diet includes invertebrates, frogs, lizards, birds, bats, and introduced small mammals (mainly black rats; Wiley 2003. Carib. J. Sci.39:189–194). *Epicrates inornatus* is widely distributed in Puerto Rico and is especially abundant in the northern karst region (Rivero 1998. The Amphibians and Reptiles of Puerto Rico, 2nd ed. Editorial de la Universidad de Puerto Rico, San Juan. 510 pp.). On 11 August 2004 at 0715 h, we found a sub-adult *E. inornatus* (ca. 100–150 cm TL) constricting and preying upon a conspecific juvenile (ca. 50 cm TL) in a karst valley in Sabana Seca (18°27'N, 66°12'W), northern coastal Puerto Rico. The juvenile was being swallowed headfirst and was ca. 1/4 consumed when first observed. We watched and photographed the boas for ca. 15 minutes before leaving and during this time the snake being consumed did not move and was presumed dead. Thus, it is unclear whether this observation of cannibalism is a result of conspecific predation or scavenging.

We thank T. M. Aide for assistance.

Submitted by **MIGUEL A. ACEVEDO-TORRES, NEFTALI RIOS-LOPEZ,** and **MARIA DEL CARMEN RUIZ-JAEN**, Department of Biology, University of Puerto Rico-Río Piedras Campus, P.O. Box 23360, San Juan, Puerto Rico, 00931-3360 (e-mail: miguel_a_acevedo@yahoo.com).

MASTICOPHIS FLAGELLUM FULIGINOSUS (Baja California Coachwhip). **DIET.** There are various reports on the diet of *Masticophis flagellum* in the USA and mainland Mexico (see Brown 1979. Brimleyana 1:113–124; Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, D.C. 668 pp.; Palmer and Braswell 1995. Reptiles of North Carolina. Univ. North Carolina Press, Chapel Hill. 412 pp.; Wilson 1973. Cat. Am. Amphib. Rept. 145.1–145.4; Wright and Wright 1957. Handbook of Snakes of the United States and Canada. Cornell Univ. Press, Ithaca. Vol. I, 564 pp.), but accounts of the feeding habits of this snake in the Baja California peninsula and offshore islands are comparatively few (Cliff 1954. Trans. San Diego Soc. Nat. Hist. 12:67–98; Grismer 2002. Amphibians and Reptiles of Baja California. Univ. California Press, Berkeley. 399 pp.; Van Denburgh 1922. Occ. Pap. California Acad. Sci. 10:615–1028; Walker et al. 1966. Copeia 1966:585–588; Ward and Clark 1988. Herpetol. Rev. 19:36–37).

On the afternoon of 18 June 2004, we found a road-killed, adult male *M. flagellum* (CIBNOR 0547, 940 mm SVL, 343 mm TL, 306.1 g [without prey item]) on Baja California Sur Road (BCS) 53, 16.3 km NW of the intersection between México Hwy. 1 and BCS 53, Municipio de Comondú, Baja California Sur, México (25°23'20.2"N, 111°50'17.4"W). Upon preserving the specimen the following morning, a female *Cnemidophorus tigris rubidus* (= *Aspidoscelis tigris rubida*, fide Reeder et al. 2002. Am. Mus. Novit. 3365:1–61; Reddish Whiptail; CIBNOR 0548, 85 mm SVL, 210 mm TL, 16.7 g) was found in the snake's stomach. The lizard, swallowed tail-first, did not appear to have any vehicle-induced wounds, and thus we believe that it was alive when captured by the snake. The snake and its prey were deposited in the herpetological collection of the Centro de Investigaciones Biológicas del Noroeste (CIBNOR), La Paz, Baja California Sur, México.

We thank Harry W. Greene for comments on the manuscript.

RODRÍGUEZ-ROBLES**, Department of Biological Sciences, University of Nevada, Las Vegas, 4505 Maryland Parkway, Las Vegas, Nevada 89154-4004, USA (e-mail: javier.rodriguez@ccmail.nevada.edu); and **PATRICIA GALINA-TESSARO,** Centro de Investigaciones Biológicas del Noroeste, S.C., División de Biología Terrestre, Baja California Sur, México (e-mail: pgalina04@cibnor.mx).

MASTICOPHIS LATERALIS EURYXANTHUS (Alameda Striped Racer). **DIET**. On 26 April 2004, at ca. 1300 h, a *Masticophis lateralis* (ca. 750 mm TL) was observed by a group of birders from a distance of about 8 m (using binoculars and spotting scopes) in White Canyon, Mount Diablo State Park, Contra Costa County, California, USA. The snake was first observed about 5 m above the ground in a Coast Live Oak (*Quercus agrifolia*) with an adult Lesser Goldfinch (*Carduelis psaltria*) in its mouth. After several minutes, the snake released the Goldfinch onto a clump of oak leaves, re-positioned itself, and began to consume the bird again. While gripping the branch with the lower third of its body, and with the bird in its mouth, the snake extended about two-thirds of its body straight up to a higher branch with its grip on the lower branch as its only support. After reaching the upper branch, it continued to climb while simultaneously swallowing the bird. The snake finished swallowing the Goldfinch after about 20 minutes, and was last seen on a branch about 6 m high near the trunk of the tree.

Masticophis lateralis are known to eat lizards, frogs, snakes, and birds (Stebbins 1985. A Field Guide to Western Reptiles and Amphibians, 2nd ed. Houghton Mifflin Co., Boston, Massachusetts. 366 pp.). However, in at least one study (Swaim 1994. Aspects of the Ecology of the Alameda Whipsnake *Masticophis lateralis euryxanthus*. Unpubl. Master's thesis. California State University, Hayward. 140 pp.), stomach contents of field-captured *M. l. euryxanthus* were exclusively lizards and documentation of specific avian prey items is lacking in the literature.

We thank R. Stallcup and B. K. Sullivan for assistance.

MICRURUS ALTIROSTRIS (Southern Coral Snake). **ARBOREALITY**. On 3 April 2004 at 1620 h at Águas Claras (30º08'N, 50º53'W), municipality of Viamão, Rio Grande do Sul state, Brazil, we observed an adult (ca. 80 cm total length) *Micrurus*

altirostris in a tree, ca. 1.5 m above the ground. The snake was supported by fine twigs and thorns and appeared to be moving toward an unidentified colubrid snake (20 cm TL) that was ca. 40 cm above it. *Micrurus altirostris* is known to prey on elongate reptiles like amphisbaenids and snakes and is primarily terrestrial (Achaval and Olmos 2003. Anfibios y Reptiles del Uruguay. Montevideo. Graphis. 136 pp.; Lema 2002. Os Répteis do Rio Grande do Sul: atuais e fosséis: biogeografia-ofidismo. Porto Alegre. EDIPUCRS. 264 pp.). This is the first report of arboreal behavior in *M. altirostris*. Arboreality in *Micrurus* has previously been reported for only four species: *M. nigrocinctus* (Schmidt and Smith 1943. Publ. Field Mus. Nat. Hist., Zool. Ser. 12:129–134), *M. fulvius* (Carr 1994. A Naturalist in Florida: A Celebration of Eden. Yale University Press, New Haven, Connecticut. 264 pp.), *M. circinalis* (Sajdak 2000. Herpetol. Rev. 31:105), and *M. surinamensis* (Hartdegen and Aucone 2001. Herpetol. Rev. 32:264).

NERODIA ERYTHROGASTER NEGLECTA (Copper-bellied Watersnake). **SIZE RECORD**. *Nerodia erythrogaster neglecta* occurs in a variety of aquatic ecosystems along the Ohio River and its tributaries. Conant and Collins (1998) reported size records for the Yellow-bellied Watersnake (*N. e. flavigaster*) (1499 mm TL), the Blotched Watersnake (*N. e. transversa*) (1473 mm TL), and the Red-bellied Watersnake (*N. e. erythrogaster*) (1575 mm TL), but did not report maximum length for *N. e. neglecta*. The previous record length recorded for *N. e. neglecta* is 1415 mm TL (Minton 1972. Amphibians and Reptiles of Indiana. Indiana Acad. Sci. Monogr. No. 3, 346 pp.). On 2 May 2004 at 1245 h, we discovered a female *N. e. neglecta* basking on a log in a swamp along the lower Cache River (Johnson County, Illinois). The snake measured (using a tailor's flexible tape) 1220 mm SVL and 1507 mm TL. Ventral scutes numbered 164. The specimen was released at its capture site.

REGINA ALLENI (Glossy Crayfish Snake). **COLORATION.** On 18 October 2002, I collected a subadult *Regina alleni* while sifting through mats of aquatic vegetation in the Hellhole Swamp (Francis Marion National Forest, Berkeley County, South Carolina). Typical *R. alleni* are dark brown dorsally, yellow or light brown ventrally with a double row of black half moons on each ventral scale. The animal I collected was solid black, except the ventral half moons and chin were white. This represents a previously unreported color phase of this species. This animal has been deposited in the Clemson University Herpetology Collection (CUSC 2200).

SISTRURUS CATENATUS CATENATUS (Eastern Massasauga). **MALE-MALE COMBAT.** Male-male combat has been documented in numerous pitvipers, and among rattlesnakes is frequently reported in the genus *Crotalus* (Carpenter 1986. Smithsonian Herpetol. Inform. Serv. 69:1–18; Shine 1994. Copeia 1994:326–346). However, within the genus *Sistrurus*, fewer reports exist and most are from captive snakes. Carpenter (1979. Copeia 1979:638–642) reported on a combat ritual between two captive male *S. miliarius*, Armstrong and Murphy (1979. Univ. Kansas Mus. Nat. Hist., Special Publ. 5:1–88) observed it in captive *S. ravus*, and Johnson (1988. *In* Rosenberg [ed.], Proceedings of the 12th International Herpetological Symposium on Captive Propagation and Husbandry, New York-New Jersey Metropolitan Area, June 15–18, 1988, pp. 71–78) observed combat in captive *S. c. catenatus*. Shepard et al. (2003. Herpetol. Rev. 34:155–156) observed aggressive behavior in the field between two male *S. c. catenatus*, one of which was already copulating when the second male arrived and did not respond aggressively. However, the intruding male exhibited behavior that resembled that reported for *S. miliarius* (Carpenter 1979, *op. cit.*).

On 22 August 2003 at 1740 h, I observed a radio-tagged male *S. c. catenatus* (M1) in combat with a previously unknown male (M2) along the Upper Wapsipinicon River, Bremer County, Iowa, USA. The two snakes were in a dense stand of *Sparganium eurycarpum*, *Scirpus validus*, *Polygonum lapathifolium*, and *P. sagittatum* ca. 1.2–1.8 m tall. When first observed, the anterior halves of both snakes were nearly vertical and their snouts were pointed upward, while the posterior thirds of their bodies were intertwined. They then began a lateral swaying movement with the anterior portions of their bodies occasionally making contact and eventually one wrapping over the other apparently in an attempt to gain superior position (Fig. 1). This behavior continued for ca. 2–3 minutes until one snake would rapidly push the other snake to the ground. The two snakes would then take 1–2 minutes to reposition and the sequence would begin again. A continuous series of these small bouts continued for ca. 55 minutes (until 1835 h). Fighting ceased when M1, after being pushed to the ground, suddenly moved away. M2 stayed at the location and searched with tongue flicking and quick head movements for ca. 1–2 minutes, at which time he moved off in a direction opposite that of M1. Rapid tongue flicking occurred during the entire period of observation, and no rattling or biting was observed. After the encounter, I captured, measured and weighed M2 (632 mm SVL, 270 g). M1 measured 586 mm SVL and weighed 286 g on 27 July 2003. A short search was made for female snakes in the area, and although none was found, a female might have been in the area but remained undetected.

To my knowledge, this is the first report of male combat in the field for *S. c. catenatus*. When compared to the display postures and topping sequence described for *S. miliarius* (Carpenter 1979,

FIG. 1. Male *Sistrurus catenatus catenatus* from the Upper Wapsipinicon River, Bremer County, Iowa, USA, engaged in combat.

op. cit.), several similarities exist, specifically, 1) displaying with the anterior portion of the body elevated in an S-shape and laterally swaying to gain superior position, 2) topping—one male gains the superior position and pushes the anterior portion of the other male to the ground in a quick movement, and 3) continuous contact of the posterior portion of the body. One notable difference was observed; an exaggerated posture of bending over backwards was observed on several occasions during this encounter. In male combat it is predicted that the larger male will typically prevail, which might result in increased reproductive opportunities for the larger male (Schuett and Gillingham 1989. Amphibia-Reptilia 10:243–266; Shine 1994, *op. cit.*). The apparent winner of this bout was M2, who was longer than M1, but weighed less.

I thank Robb Goldsberry, Wendy VanDeWalle, Stacey Carlson, John Goedeken, and James L. Christiansen for assistance. The Iowa Department of Natural Resources and the U.S. Fish and Wildlife Service provided funding.

TROPIDOPHIS WRIGHTI (NCN). **SIZE RECORD.** A male *Tropidophis wrighti* collected at Vista Alegre, Santiago de Cuba City, Santiago de Cuba Province in 1946 was maintained in captivity and fed with *Anolis* for more than two years (it died on 20 June 1949). The specimen (CTR 2; "Charles T. Ramsden" Collection deposited at Instituto de Ecología y Sistemática, Havana City Province, Cuba) measures 488 mm snout–vent length, 64 mm tail length, 14.5 mm head length, and 8.4 mm head width, and has 23 dorsal scale rows at midbody, 202 ventrals, 37 subcaudals, four spot rows, 28–31 body spots and 4-4 subcaudal spots. The previously reported maximum length for *T. wrighti* is 330 mm SVL (Hedges 2002. Bull. Nat. Hist. Mus. Lond. [Zool.] 68[2]:83–91). With this size record, *T. wrighti* becomes the second largest species of *Tropidophis* in Cuba, surpassed only by *T. melanurus*.

We thank Elier Fonseca, Lourdes Rodríguez Schettino, and Luis F. de Armas for suggestions on the manuscript.

TECHNIQUES

Herpetological Review, 2005, 36(2), 138–139.

A Simple Method to Accurately Measure Small Squamate Offspring

ERIK WAPSTRA
School of Biological Sciences, Heydon Laurence Building (AO8)
University of Sydney, NSW 2006, Australia
and
School of Zoology, Locked Bag 5
The University of Tasmania, Hobart 7001, Tasmania, Australia
e-mail: erik.wapstra@utas.edu.au

Offspring size is a key life history trait that is often reported in inter- and intraspecific comparisons in reptile studies. Tests of the evolutionary or ecological significance of offspring size rely on accurate measurements, particularly when differences might be small and yet biologically significant. This is particularly important for small squamates as a variety of "allometric engineering" techniques for altering offspring phenotype (sensu Sinervo et al. 1992) have become established for testing a variety of evolutionary hypotheses (e.g., Olsson et al. 2002; Sinervo and DeNardo 1996; Wapstra 2000; Warner and Andrews 2002). These techniques have been particularly useful for providing explicit tests generated from life history theory, such as optimum trade-offs between offspring size and number. However, observed differences in offspring size may be quite small. Mass and length are the two primary measures of offspring size usually reported. From these two measures an index of condition is often reported (residual of the regression of length against size). Although mass is easily and precisely measured using sensitive bench-top balances (± 0.0001 grams), it may fluctuate widely in response to, for example, hydration levels, recent feeding activity, and stress-induced urination and/or defecation; these variables may affect, for example, growth rate analyses (Dunham et al. 1978). In contrast, measures of length are not prone to rapid fluctuations, but are difficult to measure accurately and precisely. Measures of length are usually reported as snout–vent length (SVL) and total length. Measures of tail length are sometimes reported and are likely to become more common as it is recognized that even small variations in tail length may have important fitness consequences (e.g., Shine et al. 1997; Shine and Downes 1999).

"Water surface tension" method of length measurement

In the majority of studies where offspring size is reported, measurement of length is relatively crude (e.g., rulers ± 1 mm). In some cases, more precise methods of measurement are used (e.g., digital calipers ± 0.01 mm) but it is rarely reported how the animals were restrained to provide reliable and/or repeatable measurements. As part of an ongoing life-history study that includes a variety of experimental manipulations of offspring size (e.g., Wapstra 2000; Wapstra and Swain 2001) I have developed a technique that allows accurate and repeatable measurements of offspring size that is particularly suitable for small species and their offspring. The technique has been predominantly used on newborn Snow Skinks (*Niveoscincus ocellatus*). Snow Skinks are small (adults 3–8 g and up to 70 mm SVL), ground-dwelling skinks common in Tasmania, Australia. They are viviparous, producing a litter of 1–5 newborns that each weigh 370–650 mg with a SVL of 27–32 mm. The method is extremely rapid and simple to use and greatly reduces the incidence of tail loss that can occur in many species when they are handled for measurement.

An individual lizard is dipped in cool water and then placed in a small sealable sample bag. The surface tension of the water on the "wet" lizard causes the individual to gently adhere (dorsally and ventrally) to the bag. This gentle restraint usually has the effect of calming the lizard and minimizing movement. The bag is then placed on a flat surface with the lizard ventral side up, thus exposing the vent. Using a blunt probe it is possible to gently manoeuvre the lizard's body into an outstretched position for measurement with a pair of digital calipers (Fig 1). With some experience, repeatable measurements are obtained because it is relatively simple to estimate when the individual is uniformly straight (scales are uniformly spaced with no lateral contraction). Lizards are often stationary for approximately one minute, enough time for independent measures of SVL, total length, and tail length. Furthermore, reliable measures of head size (length and width) can be easily obtained using a low power compound or dissecting microscope fitted with an eyepiece graticule. To demonstrate the repeatability of this technique I re-measured 59 newborn *Niveoscincus ocellatus* offspring blind one day after their initial measurement (Fig. 2). There is a strong correlation between the two measurements ($r^2 = 0.9656$) and data for SVL are continuous (between 28.05 mm and 31.48 mm), rather than the categorical data (28, 29, 30, 31) resultant from cruder methods of length measurement. In some situations, it may be necessary to use means of more than one independent measurement. No side effects on newborns (even those only minutes old) have been observed with this method.

While this method has been predominantly used on small newborn Snow Skinks, it has also been successfully used for individuals up to 6 months old, providing accurate size estimates for growth analyses. Beyond 6 months, the lizards are approaching 1 g and 40 mm SVL, and are easily able to break the surface tension. The

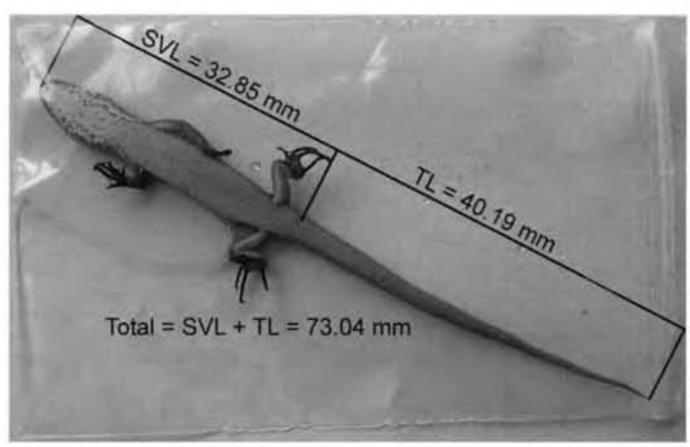

Fig. 1. Measurement of newborn Snow Skinks (*Niveoscincus*) using "water surface tension" technique. With care and the use of a blunt probe the lizard is straightened for accurate measurement of both snout–vent length and tail length.

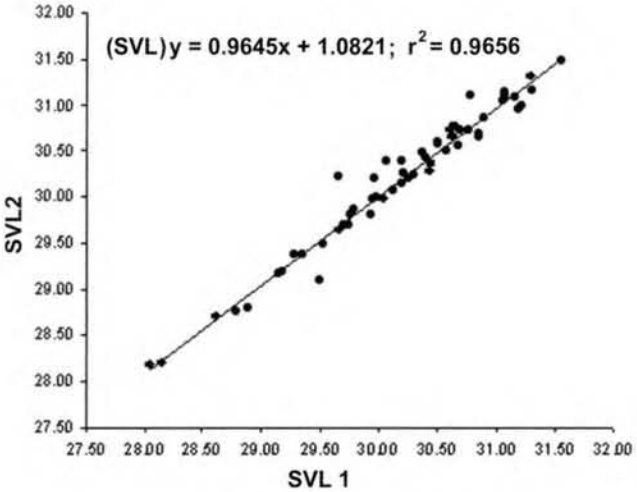

FIG. 2. Repeatability of measurements of snout–vent length (SVL) for newborn *Niveoscincus ocellatus* (SVL 1 was measured on day of birth, SVL 2 was a blind remeasure one day later; N = 59).

method has also been successful on small agamids, gekkonids, and lacertids, and is likely to be successful on a wide variety of taxa, particularly those with relatively smooth scales.

Acknowledgments.—The techniques described were developed for use in life history analyses in Snow Skinks with approval of Animal Ethics Committees from the University of Tasmania (No 94070) and Macquarie University (No. 2001/011, 2003/009). Lizards were caught under permit from Tasmanian Department of Primary Industries, Water and the Environment (Nature Conservation Branch, permit numbers 95109, 95363, and 96190). The work was supported by the Australian Research Council (DP0211364).

A Plot-based System of Collecting Population Information on Terrestrial Breeding Frogs

LAWRENCE L. WOOLBRIGHT
Department of Biology, Siena College
515 Loudon Road, Loudonville, New York 12211, USA
e-mail: lwoolbright@siena.edu

Basic information on animal populations, such as density, age or size distribution, and reproductive output, is important in order to understand their ecology and behavior. Reliable population information is essential for conservation efforts. Recent discussions of amphibian population declines (e.g., Blaustein 1994; Pechmann and Wilbur 1994) have underlined the importance of having good baseline information on as many species as possible. However, it is difficult to obtain funding for routine monitoring activities, and even when funding can be found, it is still necessary to balance the desire to collect more complete information with the constraints of time and resources. It is also important to document monitoring protocols thoroughly in order to allow for valid comparison between data sets (Oakley et al. 2003).

A variety of standardized techniques are available for use with amphibians (Heyer et al. 1994). In addition, the researcher must choose a combination of methods tailored to the focal species and the goals of the study. Many studies include population size or density as a key parameter of interest. Two recent studies have reported that capture-recapture analysis is the preferred method for estimating density of frogs in the genus *Eleutherodactylus* (Fogarty and Vilella 2001; Funk et al. 2003).

I have been attempting to quantify population parameters for a long-term study of the Puerto Rican frog, *Eleutherodactylus coqui* (hereafter the coquí), since 1981 (Woolbright 1991; 1996). The purposes of the study were to determine how populations vary through time as well as to compare different localities. Long-term population studies can provide valuable ecological information that cannot be obtained in any other way. However, the reliability of the data can be compromised when multiple data collectors use slightly different methodologies. Because there is no way to control for differences in observer perceptions, it is essential to control all other aspects of the methodology. In addition, survey methods should eliminate or control for all sampling biases that can be anticipated.

This report details the methods currently in use in my Puerto Rican study. They were developed by trial and error between 1981 and 1987, and have been fairly stable with only minor modifications since then. They include a suite of measurements that can be conveniently taken at the same time in a standardized plot-based survey. In my opinion they represent a good compromise between the need for detailed quantitative data and the need to sample multiple sites with limited time and resources. These methods work well for the coquí in the mid-elevation Tabonuco forests of the Luquillo Experimental Forest in northeastern Puerto Rico. We have more recently applied them to assessing the invasion of this species into Hawaii (Woolbright et al., in prep.). Because the coquí shares ecological characteristics with numerous other species of

Eleutherodactylus throughout the tropical Americas, the methods may also be useful to people wishing to study these species.

It is important to note that the coquí is a terrestrial breeder whose behavior does not include regular migration to breeding habitats. Migratory behavior complicates activity patterns and could introduce a variety of unanticipated biases into survey results. Therefore these methods may not be appropriate for species that migrate to breeding sites away from the normal home range.

Plot Design and Overview.—Study plots are 20 x 20 meters, divided into four 5-m strips to guide sampling. The plot size and shape were chosen to limit the number of frogs whose home ranges overlapped plot boundaries while still allowing the same observers to survey two plots per night. Two replicate plots are located at each site of interest.

Four nocturnal, time-constrained searches are conducted in each plot. I determined that number by keeping track of what proportion of adults captured each night had already been marked. Typically, after two nights of normal frog activity in a plot, more than half of the adults observed on the third night have been previously marked. However, adult activity can be lower than normal because of weather patterns, even on nights that are appropriate for surveys (see below). I added the fourth survey in an attempt to ensure that surveys included at least three nights of normal frog activity. In 1987 we conducted 14 surveys of one pair of plots to estimate the benefit of additional sampling effort. Because night 3 featured low frog activity, we reached 50% adult recaptures on night 4. After that the percentage increased slowly to a maximum of 76% adult recaptures on night 14. I concluded that additional nights of fieldwork beyond four provided diminishing returns. I also believe that it is impossible to reach 100% recaptures because of "floaters" that do not have territories but rather move through the habitat.

All adult frogs sighted during visual searches are captured and marked by clipping toes. For the long-term population study, we have used unique toe-clips because we are interested in data on the individual frog, such as growth rates and life span. However for relative density estimates, the use of cohort marking shortens the time spent marking and checking marks. Juvenile frogs are counted but not captured or marked. They can be quite numerous (361 in one plot on one night in 1992), so marking would take a significant amount of time. Their toes are too small for clipping, and I have not discovered a suitable alternative. In order to determine their size distribution, juvenile frogs are measured on one night of each survey period by holding a plastic ruler over them and assigning each juvenile to a 5-mm size class (6–10, 11–15, 16–20, 21–25 mm).

I have used capture-recapture data from adult frogs in these plots in statistical estimates of population density (as reported in Stewart and Woolbright 1996). However, as long as the probability of capture remains similar for the populations being compared, I believe that the total number of adults per four nights can be used directly as an index of relative population density (as reported in Woolbright 1991, 1996). This method suffers from a negative bias as a population estimator, and so it should be used only to compare similar plots. In addition, the magnitude of the bias is expected to increase with habitat structure and to vary with temperature and moisture conditions.

The maximum number of juveniles counted on a single night is used as an estimate of juvenile density. Although adults can be concealed by vines, epiphytes and other structure, juveniles tend to either be in the leaf litter or exposed on the herb layer close to the forest floor. At least in the interior forest in which the Puerto Rico plots are located, this layer is easily viewed. The biggest source of variation in juvenile counts from night to night is what proportion of juveniles has climbed up out of the leaf litter. Thus I believe the maximum nightly count is the best estimate we have of the total number of juveniles present. This estimate also clearly suffers from a negative bias. During periods of habitat disturbance and recovery, such as Hurricane Hugo and individual treefall events, I have been less confident in our juvenile counts because of a reduced ability to see juvenile perches clearly. This would also be a problem in more open or weedy habitats.

Adults are defined as 25 mm or more in snout-to-urostyle length (SVL). This cutoff was determined by observations of the body size at which male vocal slits open. It is intended to reflect the minimum size at which this species might be considered of reproductive age. It is considerably smaller than the actual size of reproductive adults at middle elevations of the Luquillo Forest, where calling males average 36 mm SVL and gravid females average 45 mm SVL (Woolbright 1989). Field workers carry a plastic ruler to use in determining whether or not borderline cases should be considered adults. Body size is recorded at the first capture of the survey period by placing the frog in a plastic bag, flattening it against a surface, and measuring the distance between the anterior tip of the snout and the posterior tip of the urostyle to the nearest 0.5 mm with dial calipers. Gender, reproductive condition, and pattern morph are also recorded for each adult at each capture (see below).

We also keep records of any predators seen during plot checks. We keep track of the common invertebrates that are known to eat frogs: crab spiders (genera *Stassina* and *Olios*), wolf spiders (Ctenidae), amblypigids (*Phrynus longipes*), tarantulas (*Avicularia laeta*), and scorpions (*Tityus obtusus*). The total number of predators counted per night is summed over the four-night period and used as a relative measure of predator density. We also note any sightings of rats, land crabs, cats, snakes, or other species of frogs in the plots, although these are usually too infrequent for statistical treatment.

Sound pressure level is recorded at the beginning of each night at the first plot surveyed. We have historically used a type 2 SPL meter (Realistic Company, Model 42-3019, Fort Worth, Texas) set on "C weighting" and "slow." After arriving at the plot, all headlamps are extinguished for 2 min to allow any frogs that were disturbed to start calling again. Four readings are then taken by pointing the SPL meter upslope, downslope, across grade to the right, and across grade to the left. Each position is held for 30 seconds and a minimum reading is obtained by noting the lowest point the needle hits during the 30-sec period. Frequently the four minimum readings are all the same; otherwise an average of the readings is used. Recent investigations have suggested that this technique may need to be revised (Benevides et al., in prep.).

Other data routinely collected at the beginning of each night are the time of night, wet and dry bulb readings on a sling psychrometer, a subjective statement about the amount and timing of rain in the last 24 h, and a characterization of the current condition of the leaf litter and foliage as wet, spotted, damp, or dry.

Time of night.—Based on the frogs' daily cycle of activity (Woolbright 1985), plot surveys are conducted at night, but generally before midnight. Coquíes emerge from their diurnal retreats at dark and move to their nocturnal perch sites from which they will either call or forage. Surveys do not begin until full dark when frogs have had time to get to their perches. In Puerto Rico this means starting no earlier than 1900 h in the winter and 2000 h in the summer. Depending on weather, frogs will begin to disappear from their perch sites as early as midnight. Therefore plot surveys end no later than 2400 h in the winter and 0100 h in the summer. Our standard routine is to start at the beginning of this time window and check no more than two plots per night. These times would need to be adjusted for use with a species that had a different activity pattern.

Weather.—Some frogs do not come out on extremely dry nights. The best nights for surveys are those when the leaf litter is wet and there has been at least some rain in the last day or so. Plot checks should not be done on nights that follow periods in excess of five days without rain. When heavy rain is falling, the frogs will move under cover and be hard to find. Therefore surveys should not be done on nights of continuous storms. For the occasional rainfall that lasts only a portion of the evening, we stop the search clock and turn off headlamps until the rain stops.

Traffic.—Plot checks are done by two people, walking together along the 5-m wide strips that comprise each plot. A third person can follow behind as an observer and/or data recorder, but that person should not search for frogs. More than three people at a time are not allowed in a plot because of excessive light levels that scare the frogs, as well as potential habitat damage.

Search pattern.—Each 20 x 20 m plot is divided into four 5-m wide strips to facilitate sampling. Strips generally run parallel to the contour of the plot to prevent walking up and down slope, which can lead to habitat damage. On the first night, searching should start at the top of the plot, go across the top strip, then turn around and come back the second strip, turn around and go across the third strip, turn around and come back the bottom strip. Within a strip, one person is responsible for searching from the string on one side to the middle of the strip, and the other is responsible for the middle to the string on the other side. The two searchers should consult frequently about where the middle is, and they should stay next to each other so that one does not get ahead and scare the frogs on the other side of the strip. On alternate nights, searching should start at the bottom of the plot and work to the top. On alternate nights, the two observers should switch which side of the strip they work. Note that the observer works both sides of the string dividing two strips of the plot—that is the person working the string by the next strip turns around and comes down the other side of that same string when searching the next strip. Thus, where observers start determines their location for the rest of that plot. Assuming the same two plots are done together on subsequent nights, we alternate which plot gets checked first and which second.

Searching constraints.—We count both adult and juvenile coquíes, but their perches tend to differ, so it is important to search both types of locations. Adults tend to be found on stems, tree trunks, foliage surfaces, rocks, and dead sticks from ground level up to the canopy. Juveniles are usually closer to the ground, on the small herbaceous vegetation layer from the ground up to about 50 cm. Lights should be no brighter than is necessary to see the frogs, and care is taken to avoid shining lights into areas of a plot that have not yet been searched. These are visual searches only. Searchers are instructed not to track down a calling male by the sound of his calls and not to search for frogs by opening curled leaves or other closed areas unless a frog can be seen from the outside. Violation of these restrictions can bias sex ratio patterns.

Searching time.—Searches are time-constrained. It is necessary to spend the same amount of time searching during each plot check to avoid biases introduced by people who search more or less than others. The search time for all plot checks is 1 h, specifically divided into 15 min per strip. Time is tracked using a stopwatch, and the timekeeper instructs the team to speed up or slow down in order to reach the end of the strip at the end of 15 min. If 15 min ends before the search is completed, the rest of the strip is skipped. If the end of the strip is reached before the time is up, searching continues for the full 15 min.

Search time does not include time spent handling frogs. For juveniles, this is not an issue because they are only being counted anyway. For adults, time spent handling and processing can be much greater than search time. For that reason, the stopwatch is paused upon capturing an adult and restarted when the adult is released. No searching is allowed during that time; all searching is constrained to one hour and tracked on the stopwatch.

Marking adults by toe-clipping.—Each adult captured in the plots is marked by clipping a unique combination of toes. We clip toes on all four limbs, but remove no more than one toe per limb. It is important to remove each toe completely. Toe pads regenerate, as does about one digit's worth of length. Thus if only part of the toe is removed, it will not be a distinguishable mark after it heals. Toes that have been clipped are still there and do have pads; they are just shorter than normal. In order to see old marks, a good image of the relative toe lengths on an unmarked frog is required. All field workers should spend time looking at unmarked frogs before their first survey. I do not usually include the rear "thumbs" in the toe-clipping system because they tend to lie along the leg where they are difficult to see. However during the period of time after Hurricane Hugo, when population densities were high and field seasons were more frequent, we ran out of numbers and used the thumbs to increase the number of unique marks available.

We have seen very little movement of marked frogs between plots. However, as a precaution, we use the same series of toeclips for any plots that are within about 50 m of each other.

Pattern morphs.—The coquí has a variety of different patterns (several examples can be seen in Rivero and Segui-Crespo 1992). As part of the plot data we also note the dorsal pattern of each frog marked. I use a subset of the 20-odd patterns identified by M. Stewart (pers. comm.) in the 1970's, but I omit those of her morphs that can be easily confused in the field and just use the most distinctive ones. This results in a set of morph numbers that makes no intuitive sense:

morph 5 - an irregular set of round, light or red polka dots on the back,
morph 6 - an interocular bar,
morph 9 - wild type: solid or mottled with no strong clear stripes or dots,
morph 11 - a clear light hairline stripe mid-dorsally running down the spine,

morph 11W - as above, but a wide stripe that is very noticeable, and

morph 16 - 2 dorsolateral stripes, either light or red in color.

(Note that morphs can be combined, as in 11 + 16, 6 + 11, etc.)

Determining gender.—It is not always possible to tell what sex a frog is, but there are certain clues. First, males call and have vocal sacs under their chins. Any male that has recently called will have a baggy vocal sac that is easily detected by rubbing his chin gently. Most mature males have vocal sacs that can be detected in the same way, although they will not be as baggy or obvious if the male has not been calling.

Mature females grow much larger than mature males. Although the size of all coquíes varies with locality, and notably with elevation, mature females are larger than mature males in all populations I have studied. In the vicinity of El Verde Field Station in Puerto Rico, males can get up to about 40 mm SVL and females can grow into the mid 50's (Woolbright 1989). A frog larger than 35 mm should have a vocal sac unless it is a female.

Eggs are visible through the female's body wall if present, starting with females of about 38 mm. Look on the posterior lateral surface of the abdomen adjacent to the leg for a white patch. Large eggs can be distinguished individually, while smaller ones appear as a mass. It is important to look for eggs immediately upon picking up the frog, as they will swallow air which quickly obscures the egg mass. Eggs are laid when the yolks are about 3–4 mm in diameter. If eggs are larger than this, or if they visibly contour the abdomen, it is probably a male's stomach. Egg eating is fairly common among males.

If none of these clues to sex is useful in a particular frog (usually the 25–33 mm group), then assigning gender involves guessing. Body proportions are a little different between the sexes, with females having slightly wider heads proportional to body size, and slightly longer and leaner bodies at the sizes at which males are starting to call. Experience looking at mature frogs can improve accuracy in distinguishing these differences.

Reproductive condition.—For every adult captured, we assign a reproductive condition, according to the following system. Reproductive condition is recorded as a superscript to the gender symbol (e.g., $♂^3$ or $♀^2$).

Condition 3 means that a frog is in the pool of actively reproductive animals on that night. This category includes males that are calling and females that have eggs in the 3–4 mm range. It is important to examine a male's posture before capture. If he is in the "push-up" position (Pough et al.'s 1983 "high alert") then he was calling, even though he might have stopped temporarily because of disturbance. We record males in this posture with baggy throats as callers to avoid underestimating how many frogs are calling that night. For females, the distinction between eggs big enough to lay tonight and eggs not quite big enough is subjective. However, there are not many females with 3–4 mm eggs.

Condition 2 means gender is confirmed, but the adult is not in the active breeding pool on that night. For a male this means he has a vocal sac, but was not calling. For females this means that eggs are visible, but less than 3 mm in diameter. Condition 1 means gender was not determined conclusively. Either it's too big to be a male, or the body proportions look like one sex or the other, or it's just a guess. I make many mistakes with the 25 mm frogs.

The standardized system of population monitoring detailed here provides a variety of quantified information about key characteristics of the local population. It is suitable to use for a baseline population study that can detect potentially important changes in population parameters. At the same time, it is rapid enough to accomplish on a limited budget and/or as a side project during other fieldwork.

Acknowledgments.—I thank George E. Drewry and Margaret M. Stewart for their guidance during my early attempts to count coquíes. Numerous field assistants helped develop these methods. I especially appreciate the multiple field seasons provided by George Rapp, Mike Flynn, Jennifer O'Brien, and Rusty Gonser. R. F. Inger and one anonymous reviewer provided helpful criticism of an earlier draft of the manuscript. This work was supported by grant BSR-8811902 from the National Science Foundation to the Terrestrial Ecology Division, University of Puerto Rico, and the International Institute of Tropical Forestry as part of the Long-Term Ecological Research Program in the Luquillo Experimental Forest. Additional support was provided by the Forest Service (U.S. Department of Agriculture) and the University of Puerto Rico.

Effectiveness of Three Capture Methods for the Terrestrial Sacramento Mountains Salamander, *Aneides hardii*

STEPHANIE S. HAAN

A variety of methods are used to survey amphibians, and the appropriate technique should be selected based on the goals of the study, the biology of the species being studied, and the resources available (Heyer et al. 1994). Studies of terrestrial salamanders have principally employed area- or time-constrained searches, pitfall traps with or without drift fences, quadrat sampling, and visual surveys (Corn and Bury 1990; Heyer et al. 1994). We investigated the effectiveness of three capture methods for the terrestrial Sacramento Mountains Salamander (*Aneides hardii*), a state-listed threatened species endemic to three mountain ranges in south-central New Mexico. It is critical to develop effective inventory and monitoring methods for rare species, and this study was specifically designed to select the most appropriate method to monitor *A. hardii*. Like many plethodontid salamanders, this species is particularly challenging to survey across a large number of plots because of its limited period of activity. *Aneides hardii* is only active above ground during mid-June through mid-September and is most active during the monsoonal rains of mid-July through mid-September (Degenhardt et al. 1996).

Previous studies of *A. hardii* have primarily used area-constrained searches (Borg 2001; Ramotnik and Scott 1989; Staub 1986) and time-constrained searches (Ramotnik 2001; Scott and Ramotnik 1992). However, repeatedly overturning cover objects in searches conducted seasonally can degrade salamander microhabitats (Smith and Petranka 2000). Therefore, we designed our study to compare area-constrained searches with two arrangements of pitfall traps that result in less repeated disturbance. Pitfall traps are commonly used for long-term monitoring or research plots (Corn 1994). Previous studies have demonstrated that pitfall traps are more effective at capturing certain species (Corn and Bury 1990, 1991; Enge 2001). For example, Corn and Bury (1990, 1991) had little success capturing *Aneides ferreus* in pitfall traps in the Pacific Northwest, attributing this to its close association with downed wood. In contrast, they commonly caught *Ensatina eschscholtzii*, which is generally more active on the forest floor (Corn 1994). Although *A. hardii* also is closely associated with downed wood and other cover objects, we believed that pitfall trapping might be an effective survey method. *Aneides hardii* has been unintentionally captured in invertebrate pitfall traps (Ramotnik 2001) and has been found active on the forest floor at night (D. Jones, pers. comm.).

We first evaluated, in the laboratory, the effectiveness of two types of pitfall trap lids for capturing salamanders and preventing escape. Both lid types were placed on a 2.37-L plastic bucket. One was a small plastic funnel with the narrow end removed and foam insulating tape placed around the circumference of the wide end to seal the small gap between the funnel and the plastic bucket. The other was a modified plastic lid into which we taped a flexible plastic sheet with eight evenly spaced cut flaps. We buried two traps in large tubs (N = 2) of soil from the Sacramento Mountains so that the openings were flush with the soil surface. We placed two individual *A. hardii* into each tub, and videotaped these trials over 4 h at night under low lighting. We tested six funnel-lid traps and eight plastic-flap lid traps.

We found that salamanders never escaped after entering a trap, regardless of lid type. However, lid type appeared to affect salamander entry into a trap. We observed salamanders deliberately walking partially down the entry into the funnel-lid traps, turning around, and coming back out. The plastic-flap lids tended to be more effective, as salamanders often walked onto a flap and fell in (6 of 8 [75%] tests in comparison to funnel-lid traps, 3 of 6 [50%] tests). We used the plastic-flap lid exclusively on our pitfall traps in the field.

During June 2003 in the Sacramento Mountains, New Mexico, we established four 7600-m^2 plots that were chosen for their similarity in vegetation, elevation, and disturbance history. Each plot contained three subplots with differing capture methods (Fig. 1). The subplots were separated by 50-m long buffer strips and consisted of an area-constrained search, a pitfall trap array with drift fences, and a grid arrangement of pitfall traps without drift fences. The area-constrained search subplots were 30 x 40 m (1200 m^2). The pitfall trap array with drift fences covered ca. 1232 m^2 and contained two triads with six pitfall traps each for a total of 12 traps. Each triad consisted of three 10-m drift fences constructed of 50-cm tall aluminum flashing buried ca. 20 cm in the soil, with a pitfall trap at each end of the fence. The fences radiated outward beginning 4 m from the center and were angled 120° from each other (Bury and Corn 1987). The grid design covered 1200 m^2 and consisted of 20 pitfall traps spaced 10 m apart in a 4 x 5 grid (Aubry 2000; Corn and Bury 1990, 1991; Grialou et al. 2000).

Although the two arrangements with pitfall traps differed in number of traps, they were comparable because each subplot contained approximately the same amount of sampling area. In both pitfall trap arrangements, traps were buried flush with the ground and covered with a 25 x 25 cm piece of plywood elevated with metal stakes ca. 5 cm above the edge of the trap (Block et al. 1998; Corn and Bury 1990). Moist sponges were placed in the bottom of the traps to prevent salamander desiccation (Parris et al. 1999; Rothermel and Semlitsch 2002).

Trapping occurred between 21 July and 19 September 2003, the period of the highest rainfall in the Sacramento Mountains. We operated traps for 61 days on two plots and for 47 days on the other two plots. We originally planned to operate traps on two plots during the first half of the rainy season and on the other two plots during the second half. However, because of unusually dry conditions during the first half of the season, we extended the trapping period for the first set of traps such that all traps were operated simultaneously for the second half of the rainy season, which was also drier than usual. Because we captured so few salamanders in the study, we did not disregard the captures from early in the season in order to equalize the trapping periods. We

checked pitfall traps every other day.

We searched two of the area-constrained search subplots three times, and the other two were searched twice with an interval of 14 days between searches. This unequal number of searches on subplots was also a result of dry conditions early in the study. Area-constrained searches entailed turning cover objects > 5 cm long that could be safely lifted by one person. All captured salamanders were uniquely marked with subcutaneous injections of fluorescent elastomer to examine recapture rates (Davis and Ovaska 2001). We determined the sex and measured the snout–vent length, total body length, and mass of each captured individual.

Only 77 salamanders were captured in the field experiment, preventing a statistical comparison of the three capture methods. We never recaptured a marked salamander. We captured 62 salamanders (80%) in the four area-constrained search subplots (mean, SD: 6.20 ± 5.47 salamanders captured per day), 13 salamanders (17%) in the four subplots containing pitfall trap arrays with drift fences (mean, SD: 0.06 ± 0.58 salamanders captured per day), and two salamanders (3%) in the four pitfall-grid arrangement subplots (mean, SD: 0.01 ± 0.10 salamanders captured per day). Salamanders were only captured in pitfall traps of either arrangement after a rainfall event.

Area-constrained searches required less sampling effort and yielded the highest mean number of salamanders captured per day. The amount of time required to sample and install subplot types was not equal. Both pitfall trap arrangements took less time to sample than area-constrained search subplots; however, pitfalls were surveyed more frequently, resulting in more time spent on the pitfall trap arrangements. Because of the need for repeated sampling, travel time to reach pitfall grids could greatly affect sampling effort. Area-constrained searches took ca. 3 person-hours to conduct (surveyed 2 or 3 times), and it took about 1 person-hour to check pitfall traps of either arrangement (checked 47 or 61 times). In addition, the amount of time to install pitfall trap arrangements was greater than area-constrained searches. Each array of pitfall traps and drift fences required ca. 72 person-hours to install. Fallen logs and obstacles in the soil, such as tree roots and large rocks, on our study plots made burying drift fences difficult. The grid arrangement of pitfall traps was less time consuming to install; each took ca. 20 person-hours. Corn and Bury (1990) also reported that installation of trap arrays with drift fences was time intensive, with arrays taking about twice the amount of time to install as a grid arrangement of pitfall traps without drift fences. The installation of area-constrained search subplots entailed marking the boundaries of each plot with pin flags, which took ca. 1 person-hour.

The study area received less rainfall during summer 2003 than the average summer precipitation of the previous 15 years. We obtained historical precipitation data from Cloudcroft, New Mexico, ca. 15 km from the study area (National Climatic Data Center 2004). The total precipitation for July–September 2003 was 22.12 cm, while the average total rainfall in July–September from 1988 through 2002 was 36.85 ± 8.71 cm (SD).

Ramotnik and Scott (1989) reported a mean surface density of 6 salamanders/100 m^2 from area-constrained searches conducted in 1986 and 1987 in the Sacramento Mountains. In this study, we found 1.3 salamanders/100 m^2 in area-constrained searches.

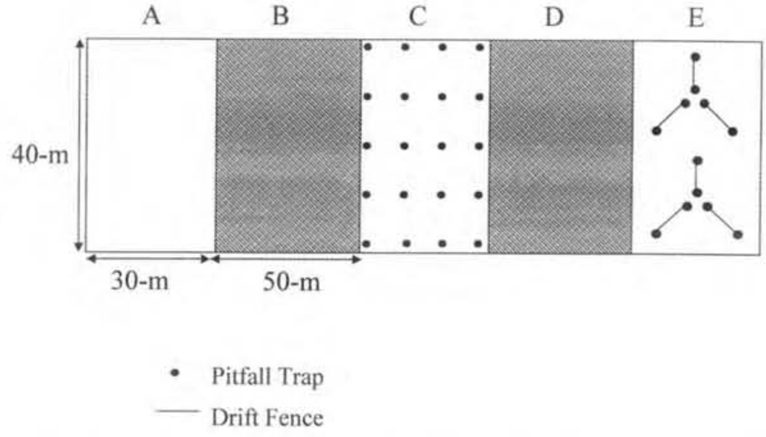

FIG. 1. Layout of the subplots within each 7600-m^2 plot. A is the area-constrained search subplot, B and D are the 50-m long buffer strips, C is the grid arrangement of pitfall traps subplot, and E is the pitfall trap array with drift fences subplot. Drawing is not to scale.

Ramotnik and Scott (1989) surveyed in August and September 1986, during which the average monthly precipitation was 13.77 ± 11.21cm (SD). They surveyed June–August 1987, but only the June precipitation data were available (12.37 cm). For comparison, the average monthly rainfall during our study period was 7.37 ± 4.35 cm (SD). Our lower capture rates during area-constrained searches may have been the result of relatively drier conditions.

Although it is difficult to make inferences about the most successful method based on these data, our results suggest that pitfall trapping is not a consistently effective sampling method for this species, especially in a dry year. When conditions are dry, plethodontid salamanders forage and seek refuge under cover objects (Feder 1983; Jaeger 1980). Feder (1983) suggested that plethodontid movement is limited by dry conditions because their skin is not resistant to water loss. Therefore, during drought conditions, *A. hardii* is most likely to be closely associated with cover objects where humidity is higher. In years of low precipitation, area-constrained searches appear to be the most reliable method for capturing salamanders. Area-constrained searches should be conducted as infrequently as possible, however, because overturning cover objects repeatedly may dessicate microhabitats.

Acknowledgments.—Many individuals from the United States Forest Service and New Mexico State University assisted with pitfall trap and drift fence installation, salamander sampling, and project advice. We especially thank Kristin Connell, Lyndi Custard, Marguerite Hendrie, Victoria Pritchard, Will Robbie, and Amy Schilz for providing field assistance on numerous occasions. George Garcia, Rene Guaderrama, and Danney Salas assisted with field logistics. Colleen Caldwell, William Gould, and J. Pat Ward provided invaluable advice on the design and implementation of this project. An earlier draft of this manuscript was greatly improved by comments from Kevin Enge, Debra Jones, Deanna Olson, Charles Painter, Cynthia Ramotnik, and an anonymous reviewer. The United States Forest Service, Sacramento Ranger District, New Mexico State University, and New Mexico Department of Game and Fish, Share with Wildlife provided funding for this research. This is a New Mexico Agricultural Experiment Station publication, supported by state funds and the United States Hatch Act.

Capture Success of Northern Map Turtles (*Graptemys geographica*) and Other Turtle Species in Basking vs. Baited Hoop Traps

CONSTANCE L. BROWNE[1]
and
STEPHEN J. HECNAR[2]
Department of Biology, Lakehead University, 955 Oliver Road

Live-trapping with baited funnel or unbaited traps is commonly used to study turtle populations and assemblages. The most common baited funnel trap is the collapsible 'hoop trap' (Lagler 1943a; Legler 1960; Plummer 1979) which consists of three or four metal rings covered by fish net and one or two funnel-shaped entrances, or some variation of this design (Iverson 1979; Kuchling 2003). Turtles are attracted by bait (usually fish) held in a perforated container suspended inside and enter a funnel-shaped entrance which hinders escape. The most common unbaited trap is the floating basking trap which capitalizes on the proclivity for basking in some species. Basking traps generally have ramps, boards, or treadles leading over a floating frame which surrounds a mesh bag or wire basket (Cagle 1950; Lagler 1943a; Plummer 1979). Turtles climb onto the boards to bask but fall into the center once disturbed and cannot escape. An important concern in any trapping program, including turtle trapping, is trap bias (Frazer et al. 1990; Ream and Ream 1966). Ideally, a trap design will not disproportionately sample any sex or age group in a population, or any individual species in an assemblage study.

Considering the relatively large size and wide distribution of the Northern Map Turtle (*Graptemys geographica*) (Ernst et al. 1994), few studies exist in the literature compared to other species. In general, map turtles are well known for their basking aggregations and wary behavior which prevents close approach and hand captures (Daigle et al. 1994; Ernst et al. 1994). Basking aggregations often occur on exposed dead trees or rocks, or on banks, in large bodies of water. Many North American freshwater turtles are omnivorous and respond to baits in traps. However, map turtles are more specialized in their diets and prefer mollusks, crayfish, and insects (Ernst et al. 1994; Lagler 1943b). Although map turtles

do enter hoop traps, they are thought to be mostly unresponsive to baits (Lagler 1943a; Plummer 1979; but see Fuselier and Edds 1994).

We designed a variation of the basic basking trap to capture Northern Map Turtles. Our objective was to compare the effectiveness of floating basking traps with standard hoop traps for capturing map turtles or other basking species.

We manufactured floating basking traps using 4" white PVC pipe and 90° elbows which were glued to provide a waterproof floating frame (ca. 2 x 4 ft). We constructed a smaller rectangular frame of 1/2-inch black flexible plastic water pipe or copper water pipe with 90° elbows. Before glueing or soldering the last joint of the small frame together, we wove 1-inch mesh polyethylene fish netting along the piping to form a bag. We attached the smaller frame to the underside of the PVC frame with plastic cable ties to provide a netted interior from which turtles cannot easily escape. To the top of the PVC frame we attached a basking platform (13 mm x 15 cm wide boards) that had hinged (door hinges) ramps leading to the water at each end. Upon our approach, turtles would run off the platform and be caught inside the floating frame. Traps were secured against drifting by either tying them to a fixed object or using a concrete block as an anchor.

The hoop traps were commercially manufactured (M. Purchase, Lawrence, Michigan; Superior Net and Twine, Thunder Bay, Ontario). Each trap had three 44-cm diameter circular (flattened bottom) steel rings, which were 42 cm apart and covered by 2.54 cm mesh fish netting. We suspended a perforated can containing fresh fish bait from the middle ring. Hoop traps were set near observed basking sites by stretching them out and fastening them to 2 x 2-inch wooden stakes so that they were mostly submerged but still permitted turtles to breathe. When stretched, a single inward pointing mesh funnel allowed turtles to enter but restricted their exit from the trap.

To compare the efficiency of basking with hoop traps, we conducted an experiment in Point Pelee National Park, Ontario (42°10'N, 82°30'W). Point Pelee contains one of the largest coastal marshes (10 km^2) in the lower Great Lakes and is characterized by ponds (1–1.5 m deep) interspersed among cattail/reed mats. Our previous research has established that the relative abundance (most to least abundant) of turtle species at Point Pelee is *Chrysemys picta*, *Chelydra serpentina*, *Graptemys geographica*, *Emydoidea blandingii*, and *Sternotherus odoratus* (Browne and Hecnar 2003).

We trapped in May and June of 2002, a time when map turtles actively bask in peripheral range locations in Canada (Daigle et al. 1994; Gordon and MacCulloch 1980). We set basking traps and baited hoop traps in a large marsh pond where we previously observed map turtle activity. Because map turtles bask in groups even when basking sites are not limited (Flaherty and Bider 1984) we tied our basking traps to emergent woody debris.

We set three basking traps for 16 days in May and 15 days in June. On the same days, we set either eight hoop traps (13 days) or seven (3 days) hoop traps in May, and eight traps (15 days) in June. To test the hypothesis of equal trap effectiveness between the two trap types (ie. 1:1 capture ratio), we compared the number of actual captures to expected captures based on trap effort using a William's corrected G-test (Table 1). In calculating expected captures, we corrected for differential trap effort by multiplying total captures by the proportion of trap days for each trap type (see Table 1). Significantly more map turtles were captured in basking traps than hoop traps in both May ($G = 176.1$, 1 df, $P<0.001$) and June ($G = 18.0$, 1 df, $P<0.001$). Significantly more *G. geographica* were captured in basking traps in May than in June ($G = 47.0$, 1 df, $P<0.001$).

TABLE 1. Northern Map Turtle captures by trap type and month. Expected captures were calculated by multiplying total captures for each month by relative trap effort (i.e., May basking trap expected captures = 74 x [48/173]).

Month	Trap Type	Captures	Effort (trap d)	Expected Captures
May	Basking	73	48	20.5
May	Hoop	1	125	53.5
June	Basking	11	45	3.5
June	Hoop	2	120	9.5

We did not capture any male *G. geographica* in hoop traps during our study. However, we captured all sex and age classes (31% male, 65% female, 4% juveniles) in basking traps. The female to male capture ratio for our basking traps was greater than 2:1. Gordon and MacCulloch (1980) captured almost the opposite ratio (61% male, 36% female, 2% juveniles) in basking traps in Quebéc. Considering that both studies were conducted at similar latitude, used similar traps, and were in the same season, the sex ratio difference likely reflects differences in actual population sex ratio rather than trapping bias.

Our basking trap was also very effective in catching Painted Turtles in areas that were not common basking spots for map turtles (Browne and Hecnar 2003). McKenna (2001) also reported higher trapping success for basking traps than hoop traps for painted turtles and captures in basking traps appeared unbiased for size or sex. However, Thomas et al. (1999) compared captures between basking and hoop traps for *Trachemys scripta* and found sex biases and seasonal differences in capture efficiency.

MacCulloch and Gordon (1978) designed a floating basking trap to study Northern Map Turtles in Québec. Their trap has a floating wooden frame and was successful at capturing all sizes of turtles without apparent sex bias. Our results highlight the effectiveness of the simple floating basking trap we designed for capturing map turtles and potentially for other basking species. It is also clear that multiple techniques should be used to minimize trapping biases among species as others have suggested (see Plummer 1979; Ream and Ream 1966). Marchand (1945) used 'water goggling' by being towed by a boat and then rapidly swimming to hand capture map turtles. Chaney and Smith (1950) located basking map turtles during the day then returned during the night to hand capture individuals from submerged vegetation. Although hand captures can be productive, they tend to be a highly biased method (Bider and Hoek 1971). Others have used binoculars or spotting telescopes to conduct visual surveys of basking map turtles from a distance (Daigle et al. 1994; Lindeman 1998). These visual surveys have low disturbance and can provide data on basking behavior or relative abundance but they do not provide as much detailed information as trapping.

Acknowledgments.— We thank C. Browne, L. Foerster, J. Hickson, and T. Zammit for field assistance, D. Hecnar and R. Losier for technical

assistance, T. Linke and V. McKay for project management, staff of Point Pelee National Park, and many volunteers. Valuable comments on the manuscript were made by R. Webb and an anonymous reviewer. Financial support was provided through Parks Canada and its Species at Risk Recovery Fund, the Ontario Premier's Research Excellence Award, and the Natural Sciences and Engineering Research Council of Canada.

A Comparison of Two Pitfall Trap Designs in Sampling Boreal Anurans

CAMERON E. STEVENS*
and
CYNTHIA A. PASZKOWSKI
Department of Biological Sciences, University of Alberta Edmonton, Alberta T6G 2E9, Canada

**Corresponding author; e-mail: stevens@ualberta.ca*

The ecology of amphibians in Canada's boreal forest is poorly documented (but see Constible et al. 2001; Hannon et al. 2002; Leclair et al. 2000; Roberts and Lewin 1979). Sound ecological techniques are needed to properly assess population sizes, distributions and habitat use patterns (Paszkowski et al. 2002). Use of pitfall traps with drift fences is a common and effective method to assess the presence and abundance of many species of amphibians (Bury and Corn 1987; Corn 1994). They are easy to construct (although installation can represent a significant time investment), generally less expensive and require less maintenance than use of funnel traps (Jenkins et al. 2003).

The conventional pitfall trap is constructed from two coffee cans (one with bottom removed) fastened together with duct tape and a plastic funnel made from a margarine container (with bottom removed) inserted at the top (Corn 1994). New research has since evaluated the effectiveness of pitfall traps to improve monitoring and increase our knowledge of sampling biases for various species and habitat types. In general, the best pitfall trap is a wider bucket or can (Mitchell et al. 1993) that is dark in color (Crawford and Kurta 2000) and has a rim or funnel to prevent individuals from escaping (Mazerolle 2003). The objective of our study was to compare in a boreal landscape the total number of anuran captures per species and age class (< 1 yr, ≥ 1 yr) between a pitfall trap similar to the conventional model (see Corn 1994) with one encompassing modifications to the previous design.

Methods.—We conducted this study adjacent to beaver ponds in the boreal foothills eco-region on the eastern slopes of the Rocky Mountains near the town of Lodgepole, Alberta, Canada (53°06'N, 115°19'W) during summer 2003. Common species in the region are the Wood Frog (*Rana sylvatica*), Boreal Chorus Frog (*Pseudacris maculata*), Western Toad (*Bufo boreas*), and Common Garter Snake (*Thamnophis sirtalis*; Russell and Bauer 2000). All three species of anurans were heard calling on the study ponds in the spring prior to pitfall trapping.

Our study compared two types of pitfall traps: an 'old' versus 'new' model. The 'old trap' was similar to, but smaller than, the one described in Corn (1994): we used 1.5 coffee cans (1 kg size) rather than 2 coffee cans (1.36 kg size). The inserted funnel in the coffee can was a margarine container (907 g) with the bottom cut out (Fig. 1). The 'new trap' was a 7.6-L plastic bucket; black in color with a soft-sloping funnel constructed from polyethylene plastic (i.e., vapor barrier) and duct tape (Fig. 1). This trap type was wider than the old model (23 cm vs. 15 cm diam). However, trap depth, diameter of the funnel hole, and distance of the funnel hole to the bottom of the trap were similar between trap types

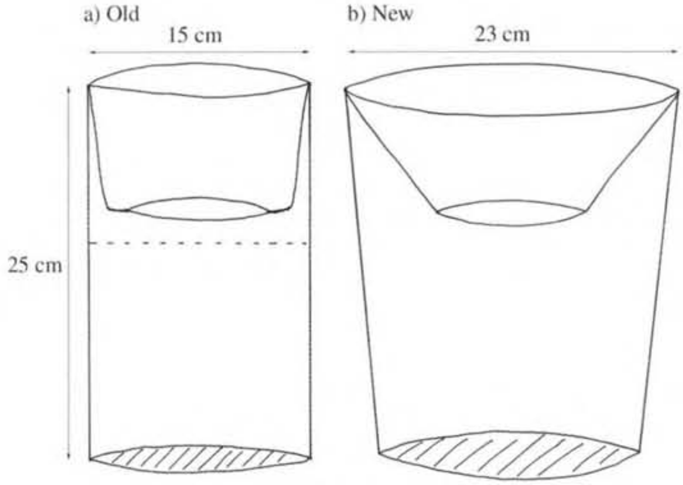

FIG. 1. Pitfall trap dimensions and design for the 'old trap' (Fig. 1a) made from 1.5 coffee cans (1 kg size) with a margarine container (hard) funnel, and the 'new trap' (Fig. 1b) constructed from a 7.6-L black plastic bucket with a sloping, polyethylene (soft) funnel.

(Fig. 1). A small quantity of moss was added to the bottom of each trap to keep animals moist and shaded (we did not use cover boards above traps). A stick (1.0 cm diam) was also inserted into each trap to allow small mammals to escape (Perkins and Hunter 2002). Traps were installed in pairs along drift fences; each fence consisted of one new trap placed at one end and one old trap at the opposite end. The drift fence was a polyethylene sheet 5 m long and 30 cm wide above ground with ca. 5 cm of plastic buried in the soil. All fences were 5–10 m from, and parallel to, the shoreline associated with four beaver ponds within a 200 km^2 study area. Approximately 20% of the shoreline of each pond was covered with drift fences resulting in 10, 9, 8, and 6 fences randomly located on the four ponds for a combined total of 33 trap pairs. Pitfall traps were opened from June 28 to July 30, 2003 and checked every 3–4 days.

Captured anurans were identified to species and age class (< 1 yr or young-of-year and ≥ 1 yr or "adult") and a sample of individuals were measured for snout–urostyle length (SUL) and mass. Individuals categorized as young-of-the-year (YOY) were < 21 mm SUL for Boreal Chorus Frogs and < 27 mm SUL for Wood Frogs and Western Toads, or had remnants of a larval tail (in some cases anurans with a larval tail were counted but not measured for SUL). All anurans were released 5–10 m from their point of capture. Animals were not marked (e.g., toes clipped) because previous pitfall trapping in 2001 and 2002 resulted in very low recapture rates for anurans in the area (< 2%; C. E. Stevens and C. A. Paszkowski, unpubl. data).

We determined if there were differences in the total number of individuals captured per species and age class between old and new traps from all 33 fences combined (N = 33) using a Wilcoxon paired-sample test. We chose this analysis because each data set consisted of a non-normal distribution even after square-root and logarithmic transformations, and because trap types were installed in pairs to account for possible microhabitat differences among fence locations that can affect capture rates (deMaynadier and Hunter 1999; Melbourne 1999). We accepted significance at the 5% level.

Results.—Sixty-six pitfall traps captured 1274 anurans: 1111 YOY Wood Frogs, 84 YOY Boreal Chorus Frogs, 43 adult Wood Frogs, 32 adult Western Toads, 4 adult Boreal Chorus Frogs, 0 YOY Western Toads (Table 1), and 0 snakes. Significantly more individuals were captured in new versus old pitfall traps for adult Wood Frogs (z = -2.28, $P = 0.022$) and YOY Boreal Chorus Frogs (z = -4.03, $P < 0.001$; Table 1). However, there were no significant differences in numbers caught between trap types for YOY Wood Frogs (z = -0.13, $P = 0.893$) and adult Western Toads (z = -1.28, *P*

TABLE 1. Total number of captures and number of drift fences that captured higher numbers of individuals in 'new pitfall traps' (i.e., plastic buckets with polyethylene funnels) versus 'old pitfall traps' (i.e., coffee cans with margarine funnels) adjacent to 33 drift fences (5 m length) per anuran species and age class on four beaver ponds in west-central Alberta during 28 June to 30 July 2003. *P* determined by a Wilcoxon paired-sample test and reflects differences in captures between trap types. Mean (± standard error) snout–urostyle length (SUL) for each category is based on a sample of captured individuals that were measured during the trapping period.

	Anurans < 1 yr old				Anurans ≥ 1 yr old

					N = 12	N = 20		

na = Value not available because of low number of captures

* Relatively large value due to one new trap that captured 168 individuals, whereas the paired old trap caught 60 YOY wood frogs only

† Number of fences or trap pairs with higher captures in the new trap, including number of fences with equal captures between trap types in brackets

= 0.202; Table 1).

Discussion.—The new pitfall trap design was as effective or more effective in trapping boreal anurans than the more commonly used coffee can design (e.g., Corn 1994). This difference might reflect anuran avoidance of the silver color inside the coffee cans or the white color associated with the margarine container used as the funnel (Crawford and Kurta 2000). In addition, adult ranids may avoid the narrower traps (i.e., coffee cans) by jumping over the hole. The structure and shape of funnels in pitfall traps could also influence their effectiveness in trapping anurans. For example, the margarine container in our study had a hard rim or lip that could provide a solid platform for individuals inside the trap to grasp with their forelimbs or to rest on, rather than falling into the deeper can, particularly for YOY Boreal Chorus Frogs (CES, pers. obs). In contrast, the funnel in the plastic bucket was a soft or flexible polyethylene sheet with a constant sloping surface that lacked distinct surfaces for support (Fig. 1).

Very few adult Boreal Chorus Frogs and no YOY Western Toads were captured in our study. Hylids, in general, are difficult to sample with pitfall traps because of their ability to climb vertical structures (Dodd 1991). The lack of captures of YOY Western Toads, however, may reflect the fact that partial fencing of ponds failed to intercept individuals that emerged in a non-uniform pattern rather than failings of the trap designs. For example, newly metamorphosed toads may have emerged from concentrated locations in the pond where the water was warm or highly oxygenated (Noland and Ultsch 1981). It is also possible that the beaver ponds in our study were poor larval environments for toads (e.g., too cold, inadequate food) leading to low juvenile recruitment to metamorphosis.

Our field experience with both types of pitfall traps suggests that the plastic bucket-polyethylene funnel design is easier to construct than the one made from a coffee can and margarine container. The special cutting device and time needed to remove the bottom of coffee cans and cut tin to create the 1.5 coffee can was not required for the plastic bucket. In addition, large numbers of plastic buckets can be stacked because of their tapered design (Fig. 1) and carried into field locations with greater ease than when using non-stackable coffee cans. Cans can also rust with extended use and eventually need to be replaced. Finally, although coffee cans and margarine containers can be obtained for free, the costs of plastic buckets and polyethylene plastic are relatively low when bought in large quantities: \$2 per 7.6-L plastic bucket, and \$13 per 46 m^2 roll of polyethylene plastic (Cdn dollars).

In summary, the new model (plastic bucket with flexible polyethylene funnel) was a better pitfall trap than the old model (coffee can with margarine container) both in terms of ease of use and trapping performance. Funnel designs may play a key role in reducing the number of hylids and large ranids that escape from traps. Understanding the biases of various methods and improving ecological techniques to monitor more accurately population trends is critical to the conservation of anurans in boreal habitats.

Acknowledgments.— Financial support was provided by Alberta Challenge Grants in Biodiversity through the Alberta Conservation Association (ACA) and Circumpolar/Boreal Alberta Research Grants through the Canadian Circumpolar Institute. We are grateful for Rayna's assistance in the field and logistical support provided by Drayton Valley division of Weyerhaeuser Canada Ltd., and Randall Lynch with Camp Brazeau, AB (www.campbraz.com).

Attachment of Radio Transmitters in a Rock Iguana, *Cyclura lewisi*

RACHEL M. GOODMAN

University of Tennessee, Knoxville, Tennessee 37996, USA
e-mail: rmgoodman@utk.edu

Tracking with radio telemetry is an important tool for studying aspects of the behavior and ecology of animals, including movements and habitat use. In endangered lizards, such as iguanas of the genus *Cyclura*, radio tracking may yield valuable insights about habitat and area requirements that may aid in management and conservation. Radio tracking is a particularly important monitoring technique for *Cyclura* because they have large home ranges (up to 9 ha) that may shift seasonally (Rose 1982; Wiewandt 1977; Mitchell 1999). Unfortunately, no optimal method of attaching radio transmitters has been demonstrated for *Cyclura*, although many have been attempted.

Cycluran iguanas are found on islands throughout the West Indies, where they commonly live in habitats with rocky limestone substrates, using jagged rock sinkholes as retreats (Alberts 2000). This rocky substrate, and possibly the low-growing vegetation often found on these islands, contribute to the frequent detachment and loss of radio transmitters attached externally to these iguanas. The following methods of external attachment have been tried in different species of *Cyclura*, with varying levels of success: waist belts (Mitchell 1999), neck collars (with hatchlings, N. Perez, pers. comm.), vests worn over the anterior portion of the body (Hates et al. 2000), duct taping transmitters to tails (C. Knapp, pers. comm.), and suturing transmitters below dorsal crests (F. Burton, pers. comm.).

Two additional methods have been used to secure radio transmitters in *Cyclura*: feeding transmitters in food to iguanas (Christian et al. 1986, Goodyear and Lazell 1994) and surgically implanting transmitters into the body cavity (F. Burton, A. Alberts, pers. comm.). The former method is only useful for short-term data collection, as the transmitter is expelled during defecation after 4–7 days (Goodyear and Lazell 1994). The latter method, which has been used in several other lizards (Schauble and Grigg 1998; Sound and Veith 2000; Wikelski 1999), seems the best way to ensure long-term monitoring of an iguana because the transmitter is secured inside of the body. However, the implant procedure requires anesthesia and surgery, which increase risk to the animal and cost to the researcher due to the need for veterinary staff (desirable and often required for surgical implantation because all species of *Cyclura* are protected). Furthermore, no studies have been published on the long-term effects of transmitter implantation on lizards, so the risk of decreased fitness due to transmitter implantation is unknown. Because of the long life span in *Cyclura* (up to 60 years, Iverson et al. 2004), negative consequences of transmitter implantation could take years to manifest.

During a study on the spatial ecology of *Cyclura lewisi* (formerly *C. nubila lewisi*, see Burton 2004) on Grand Cayman in 2002, I used two methods to attach radio transmitters to iguanas. Transmitters were attached to five large males (36–49 cm SVL, 80–118 cm TL, 2.2–5.1 kg) in 11 instances by suturing below the posterior dorsal crest (Fig. 1). Transmitters were attached to seven females and one small male (27–38 cm SVL, 69–93 cm TL, 0.9–2.7 kg) in 17 instances by gluing to the posterior dorsum. Suturing was not used with these smaller iguanas because their smaller dorsal crests may be vulnerable to tearing if the transmitters became caught on rocks or vegetation. Suturing radio transmitters to animals has been previously described in fish (e.g., Erkinaro et al. 1999) and snakes (e.g., Ciofi and Chelazzi 1991). To my knowledge, however, no published study has reported suturing transmitters below the dorsal crest in lizards. Therefore, the purposes of this paper are to describe the technique of suturing transmitters to iguanas, to assess the impacts of this method on the lizards in this study, and to compare the short-term reliability of gluing and suturing methods.

Iguanas were not anesthetized for either method of attaching transmitters, but were fully restrained both manually and with large cloth straps secured with Velcro®. For method 1, radio transmitters (Holohil Systems, Ltd. model AI-2, cylinder 45 mm x 15 mm diameter with whip antennae 23 cm length, 6 month battery) that had a flat metal mounting plate (75 mm x 8 mm) on the bottom were encapsulated in liquid plastic. This unit was glued to the dorsum of the iguana just anterior to the base of the tail alongside the dorsal crest using cyanoacrylate gel. Other studies with lizards have used similar methods of attaching transmitters externally with glue or epoxy (Cuadrado 1998; Griffiths and Christian 1996; Sabo 2003).

In method 2, the posterior dorsum of the iguana was first cleaned with 70% isopropyl alcohol. Then the transmitter (same model as above) was sutured below the dorsal crest in the following manner, which is similar to a bead-tagging technique described by Rodda et al. (1988) that is currently used by many researchers working with *Cyclura*. The dorsal crest of the iguana was held firmly in hand while a 16-gauge needle was used to puncture the skin just below the origin of the dorsal scales. The needle was pushed through neoprene pads on each side of the crest, and nylon-coated steel leader wire (60 lb strength, 0.7 mm diam) was then threaded through the needle and pads. This was done in two places on the posterior dorsal crest, and the needle was subse-

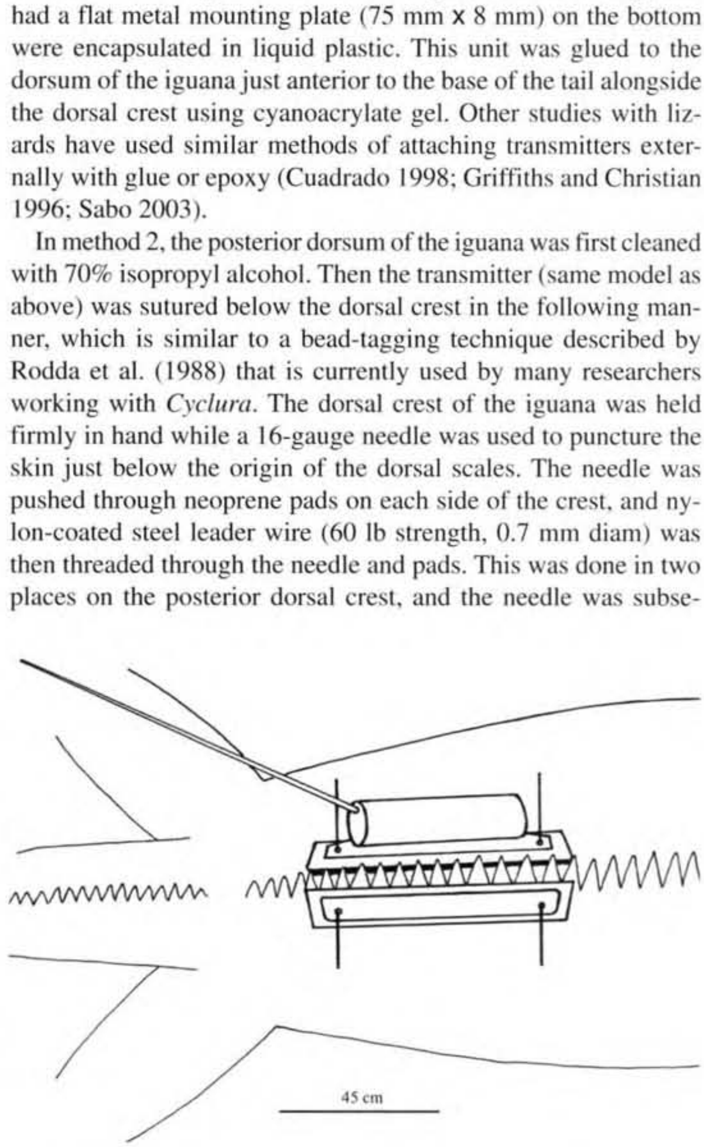

FIG. 1. Diagram of the method used to suture a radio transmitter below the dorsal crest of an iguana.

quently removed from the skin, leaving the leader wire in place below the dorsal crest. Next, the radio transmitter and backing plate were attached on opposite sides of the dorsal crest by leading the wire through the holes in each. Glass beads (ca. 4 mm diam with ca. 1.4 mm diam hole) were threaded onto the terminal portions of the wire, and the wire ends were secured with leader sleeves. The glass beads are not a necessary part of the design, but were added in this case because the holes in the radio transmitter mounts and backing plates were larger in diameter than the leader sleeves. The total mass of either type of transmitter package before gluing or suturing averaged 35–40 g, which was less than 5% of the body mass of iguanas and therefore acceptable within common standards (Macdonald and Amlaner 1980).

No adverse effects of gluing transmitters to iguanas were noticed. These transmitters were removed from iguanas by cutting them out of the plastic casing, leaving only a small patch of plastic on the dorsum which fell off before or during the next shedding. The effects of the suturing technique involved occasional slight bleeding immediately after puncturing the skin, and small puncture wounds evident upon removal of transmitters. No infection of the puncture sights was noted during or after radio tracking iguanas in this study. One year post-removal, these wounds had healed and were small when compared to scars resulting from intraspecific interactions. In some cases, puncture wounds were slightly expanded during wear (still < 2 mm diam), probably because the transmitter had become caught on vegetation and pulled away from the body in the animal's struggle to free itself. I witnessed such events wherein iguanas became temporarily entangled in vegetation because of radio transmitters, but in no case did this affect the movement of an iguana for more than one minute. Future use of the suturing method should modify this study's design to minimize the potential for transmitters to catch on rocks or vegetation. Transmitters should not have sharp edges or any places where vegetation could become caught, especially on the anterior side.

One major assumption in radio tracking studies is that animal movements are not affected by the techniques that researchers use (White and Garrott 1990). Although I could not verify this assumption for all individuals, the following observations lead me to believe that radio transmitters did not heavily influence the behavior of iguanas. No iguana was observed biting or excessively scratching or inspecting the radio transmitter and associated attachment site on the body. Iguanas were always more wary of researchers after capture and handling, but there was no evidence that this was more pronounced in cases where transmitters were attached (using either method). Iguanas did not appear to respond to the puncture sites after transmitters were sutured to them. In fact, one male was observed successfully copulating with a female less than fifteen minutes after having a transmitter sutured to him.

Only the short-term reliability of gluing and suturing methods was assessed because the number of radio transmitters was limited in this study and transmitters were periodically removed and reused on different iguanas. Eight of 17 (47%) transmitters that were glued to iguanas fell off within two weeks. Of the remaining glued-on transmitters, several were removed within one month for use on other iguanas, and four were removed after 30 days. One transmitter that could not be retrieved was still on an iguana when the study ended 45 days after attachment by gluing.

Only two of 11 (18 %) transmitters that where sutured to iguanas fell off within two weeks. These were the first two transmitters to be attached with this method, and loss resulted within two days from a failure to completely clamp the leader sleeves securing the apparatus. Once this problem was resolved, all sutured transmitters remained attached until removed intentionally by a researcher. Of these remaining nine transmitters, three were removed at 16–17 days, five were removed at 29–32 days, and one was left on as a long-term trial. Unfortunately, this iguana was run over by a vehicle 48 days after transmitter attachment. One of the sutures ripped through the dorsal crest of the iguana during the accident, and the transmitter was removed immediately afterward.

The two methods of transmitter attachment were used on different sized iguanas, and I could not investigate whether there was any relationship between body size and length of transmitter attachment. However, I believe that the low reliability of glued-on transmitters was because of the attachment method and not the body size of iguanas, inferred because of the way in which transmitter detached. Transmitters that had been glued-on detached at the site of gluing because of a failure of the adhesive or the sloughing or tearing off of old skin that was about to shed. Presumably these could occur in all sexes and sizes of iguanas. Additionally, if greater movement rates were responsible for increased snagging and detachment of transmitters, we would expect to see the opposite results of those presented here on reliability of methods, as male *C. n. lewisi* have greater or equal movement rates than females (Goodman 2004).

Burton (pers. comm.) used a similar suturing technique in 1993 to attach transmitters to two *C. n. lewisi*, except that design lacked the neoprene pads and backing plate incorporated in the current study. One of these transmitters remained attached for six months, while the other remained attached for at least two months, after which the iguana disappeared. Based on Burton's experience in 1993 and the results of radio tracking conducted in 2002, suturing transmitters to the dorsal crest seems more reliable than gluing transmitters to the dorsum with cyanoacrylate gel.

The main potential drawback to the suturing method, transmitters getting snagged on rocks or vegetation, was not a large problem in this study and can probably be further minimized with slight design improvements. Benefits of suturing transmitters to iguanas, compared to other attachment methods include cost efficiency, short-term attachment reliability, and less invasiveness than internal implantation. Although long-term safety and reliability of attachment need to be examined in more detail, this method of suturing radio transmitters to iguanas appears promising for researchers working with large lizards.

Acknowledgments.—The National Trust for the Cayman Islands and the Queen Elizabeth II Botanic Park granted permission to conduct the study and provided support. Thanks to Glenn Gerber and Frederic Burton, who recommended the idea of suturing radio transmitters to the dorsal crests. I am also grateful to A. C. Echternacht, Burton, and Adam Paulek for assisting in design and implementation of this technique and to Burton, Echternacht, Gerber, and an anonymous reviewer for comments on this manuscript. Methods used in this study were approved by the University of Tennessee Institutional Animal Care and Use Committee.

Comet Assay Used to Detect Genotoxic Effects of Mining Sediments in Western Toad Tadpoles (*Bufo boreas*)

Water contaminated by mining sediments can have lethal and sublethal effects on amphibians (e.g., Hopkins et al. 1997; Lefcort et al. 1998; Porter and Hakanson 1976; Rowe et al. 1998). However, not all mining sediments are alike. Depending on the parent-rock material, pH levels, and hydrological patterns, the heavy metal concentrations of sediment effluents can be highly variable (Robb and Robinson 1995) and, consequently, range from being highly toxic to relatively benign for amphibians. Thus, different management strategies ranging from intensive reclamation to no action may effectively reduce the threat from mining sediments (Robb and Robinson 1995).

Amphibian survivorship, development, and behavior studies can assess the toxicity of mining sediments (e.g., Lefcort et al. 1998; Porter and Hakanson 1976; Rowe et al. 1998). However, such studies could take weeks to months to complete reducing the number of sites examined in a field season. A more time efficient approach may utilize genotoxic assays of amphibian larvae *in situ* (or caged for short time periods) to assess the toxicity of sediment effluents. One promising technique is single-cell gel (SCG) electrophoresis.

Singh et al. (1988) first developed alkaline SCG electrophoresis for quantification of low levels of DNA damage in human lymphocytes. The technique is referred to as the "comet" assay because the DNA fragments from affected cells migrate further than intact DNA, resulting in a streaked appearance. The length to width ratio of the streak is an indication of the DNA damage (Singh et al. 1988). The comet assay has been modified for many plants and animals for genetic ecotoxicology research (Cotelle and Férard 1999). For amphibians, the comet assay has been used *in situ* and in field and laboratory studies to detect DNA fragmentation in nucleated erythrocytes resulting from exposure to organic toxicants such as herbicides, pesticides, and petrochemicals (Clements et al. 1997; Ralph et al. 1996; Ralph and Petras 1997, 1998a,b). However, it is not known whether this technique is effective for assessing the toxicity of heavy metals on amphibians (but see De Boeck et al. 2000 for effects of heavy metals on human lymphocyte DNA).

We examined the effectiveness of the comet assay to detect the toxic effects of mining sediments on Western Toad (*Bufo boreas*) larvae in Montana. We first used survival and growth studies, in the field and in the lab, to demonstrate the toxic effects of sediments from an abandoned gold/silver mine. We then used the comet assay to test for DNA fragmentation resulting from exposure to the same mining sediments.

The abandoned Nellie Grant Mine is ca. 38 km S of Helena, Montana, in the Helena National Forest. Before reclamation work in 1998, water drained ca. 200 m from the mine site into a multi-pooled, sedge-grass wetland (Frohner Meadows) through piles of waste rock and mine tailings. Sediment and water samples taken in 1993 were acidic (mean pH = 6.0) and contained significant levels of arsenic, lead, and other heavy metals (Blundell et al. 1997a,b). The primary drainage from the mine bisected Frohner Meadows, heavily contaminating the lower elevation pools while leaving the upper elevation pools relatively unaffected. Our amphibian surveys in 1998 and 1999 found no breeding populations in the lower pools of the wetland, whereas Western Toad, Columbia Spotted Frog (*Rana luteiventris*), and Long-toed Salamanders (*Ambystoma macrodactylum*) were found breeding in the upper pools.

In the summers of 1998 and 1999, we reared Western Toad tadpoles in field enclosures made of nylon window screening with a wood frame (100 x 50 x 50 cm). The tadpoles were collected from the upper region of the wetland within a day of hatching. We placed six replicate enclosures in pools upstream from the effluent and six replicate enclosures in pools downstream from the effluent (i.e., 12 enclosures total). We introduced 30 tadpoles into each enclosure in 1998 and 50 tadpoles into each enclosure in 1999. We left the enclosures undisturbed for 21 d in 1998 and 28 d in 1999, and then counted the number of tadpoles surviving in each enclosure. We used an independent samples t-test to test for differences in the proportion of surviving tadpoles between the upper and lower regions of the wetland. One replicate enclosure in the upper region in 1999 was eliminated from analysis after being destroyed by a moose.

We collected Western Toad eggs from six clutches in June 2000 from Park Lake (32 km S of Helena, Montana), a site that receives no runoff from the Nellie Grant Mine. We housed the eggs in 38-L aquaria in the laboratory until hatching. After hatching, the tadpoles were divided and used in two laboratory studies: a survivorship/growth study and a comet assay study.

We collected sediment from a pond in the lower region of Frohner Meadows to use as experimental substrate in both studies. "Playground" sand (purchased at a hardware store and washed several times with water) was used as a control substrate. For both studies, experimental chambers consisted of 3.8-L aquaria with ca. 1 cm of substrate (either experimental or control) covering the bottom. We filled the aquaria with dechlorinated water and allowed the sediment to settle for 24 h prior to tadpole introduction.

For the survivorship and growth study, we examined three pH levels with the two substrate treatments, resulting in six treatment conditions: Frohner sediment pH 5.0, pH 6.0, and pH 7.0, and sand substrate pH 5.0, pH 6.0, and pH 7.0. We replicated each treatment four times. The 24 aquaria were arranged randomly on a laboratory bench. We then placed ten tadpoles (stages 25–30; Gosner 1960) in each aquarium. We adjusted the pH of each aquarium daily and fed the tadpoles 0.25 g of rabbit pellets every other day. After 14 d, we counted and weighed each of the survivors and calculated the average mass of survivors in each aquarium. We used two-factor analysis of variance (ANOVA) to test for the effects of sediment type and pH on tadpole mass and on the proportion of tadpoles surviving.

For the comet assay, we examined two pH levels (5.0 and 7.0) with the two substrate treatments resulting in four treatment conditions (the absence of the pH 6.0 treatment level in the comet assay was logistically necessary to reduce the number of aquaria requiring daily maintenance). We established two replicates of each treatment for a total of eight aquaria and introduced 10 tadpoles (stages 30–36; Gosner 1960). Again, we adjusted the pH daily, and fed the tadpoles every other day. After 14 d, surviving tadpoles were euthanized and bled for use in the comet assay (six individuals per treatment condition).

For the comet assay, we generally followed the procedure described by Ralph et al. (1996). We labeled frosted microscope slides for each individual tadpole, treatment type, and direction of electrophoresis and then coated each slide with a layer of 1 percent normal melting point agarose prepared with 10 mM phosphate buffered saline (PBS, pH 7.4) and microwaved for 25 sec. Slides were placed in an Immuno Frame, and allowed to dry in the refrigerator at 4°C.

We performed all subsequent steps in the dark under dim yellow light to prevent DNA damage. Tadpoles were humanely euthanized, blotted dry with a paper towel and then minced with scissors into a lid of a Coplin jar. We then added 10–12 drops of 10% Hank's balanced salt solution (HBSS, Ca^{2+} and Mg^{2+} free) and allowed the contents to sit for 10 min. Nucleated erythrocytes represented the majority of harvested cells.

We pipetted the suspension of blood cells into a 1500 ml microtube. From this stock, we pipetted 300 ml into a separate microtube. We then placed a drop of the remaining stock on a microscope slide and examined it at 400x to make sure that blood cells were present and that there were no more than three to four cells in a field of view at this magnification. If too many cells were present, we diluted the sample with HBSS.

We prepared low melting point agarose (0.5%) with PBS and microwaved it for 20 sec. Once the agarose had cooled to 37°C, we pipetted 600 ml into each microtube sample containing a 300 ml blood cell sample. Tapping the tubes mixed the resulting 900 ml of solution, which we then pipetted onto a frosted microscope slide prepared earlier. To prevent loss of the agarose mixture, we left the slides on the Immuno Frame. Coverslips were placed on the slides and the entire Immuno Frame was transferred to a level surface in a refrigerator (4°C) and left for 2 h to allow the agarose to polymerize.

To allow DNA fragments in the nucleus to migrate, cell membranes were lysed before electrophoresis using a mixture of 30 ml of 5 M sodium chloride, 15 ml of 400 mM disodium ethylenediamine-tetra-acetate (EDTA, pH 10), 6 ml of 100 mM Tris (hydroxymethyl) aminomethane hydrochloride (Tris-HCl, pH 10), 6 ml of dimethyl sulfoxide (DMSO) and 0.6 g of N-lauroylsarcosine, adjusted to a pH of 10 and final volume of 60 ml. We placed the sample slides into staining trays with the lysing solution for 2 h at room temperature.

We made an electrophoresis buffer by mixing 30 ml of 10 N sodium hydroxide and 5 ml of 200 mM EDTA (pH 10), adjusted the pH to be greater than 13, and then brought the volume to 1 L. We placed the sample slides in BioRad, Mini-Sub Cell GT gel units, and immersed them in about 1.5 cm electrophoresis buffer, for 15 min at 4°C. We then ran the units at 4°C for 30 min and regulated the current at 265 mA with the BioRad, Power Pac 1000 power supply. Following electrophoresis, we neutralized the slides

with two washes (each 5 min in duration) by immersing them in staining trays containing 30 ml of 400 mM Tris (pH 7.5) at room temperature.

We prepared a stock stain by dissolving 0.7 mg bis-benzimide in 0.25 ml of Tris-EDTA (TE) buffer. The working solution was a 1:1000 dilution of the stock in TE buffer. We stained slides by immersing them in staining trays with 25 ml of the working solution for 2 h at room temperature.

We examined each slide at 400x magnification using an epifluorescence microscope (Nikon EFD-3) equipped with a 330–380 nm excitation filter, a 420 nm barrier filter, and a 400 nm dichroic mirror. After beginning at an arbitrary point, we scanned slides in a straight line and measured the first 25 nucleic DNA clusters encountered that did not overlap other clusters or their "tails." We measured the length and width of each nucleic DNA cluster with an ocular micrometer and calculated the average length-to-width ratio for each individual tadpole. We then used two-factor ANOVA to test for the effects of substrate type and pH on the length-to-width ratio of DNA clusters.

The 1998 and 1999 field studies suggested that the effluent draining from the Nellie Grant Mine was lethal to Western Toad tadpoles. The proportion of tadpoles surviving in enclosures located above the effluent (mean ± SE: 0.81 ± 0.06) was higher (t statistic = 4.8, df = 9, $p<0.001$) than the proportion of tadpoles surviving in enclosures below the effluent (0.14 ± 0.12).

Sediments from the lower region of Frohner Meadows also had lethal and sub-lethal effects on tadpoles reared in the laboratory in 2000 (Table 1). The proportion of tadpoles surviving was higher in aquaria with sand substrate (0.93 ± 0.07) than in aquaria with sediment from Frohner Meadows (0.56 ± 0.08). The average mass of surviving tadpoles was higher in aquaria with sand substrate (0.27 g ± 0.03) than in aquaria with sediment from Frohner Meadows (0.08 g ± 0.01). The pH levels had no significant effect on survivorship or mass (Table 1).

Sediments from Frohner Meadows interacted with pH to influence the length-to-width ratios of DNA clusters (Table 1). Overall, length-to-width ratios were larger in aquaria with sediment from Frohner Meadows than in aquaria with sand substrate (Fig. 1; Tukey HSD post-hoc test, $p<0.001$). There was no difference in length-to-width ratios between treatments of pH 5.0 versus pH 7.0 in aquaria with sand substrate (Fig. 1; Tukey HSD, $p = 0.997$). However, the pH 7.0 treatment had a larger length-to-width ratio than the pH 5.0 treatment in aquaria with sediment from Frohner Meadows (Fig. 1; Tukey HSD, $p<0.001$).

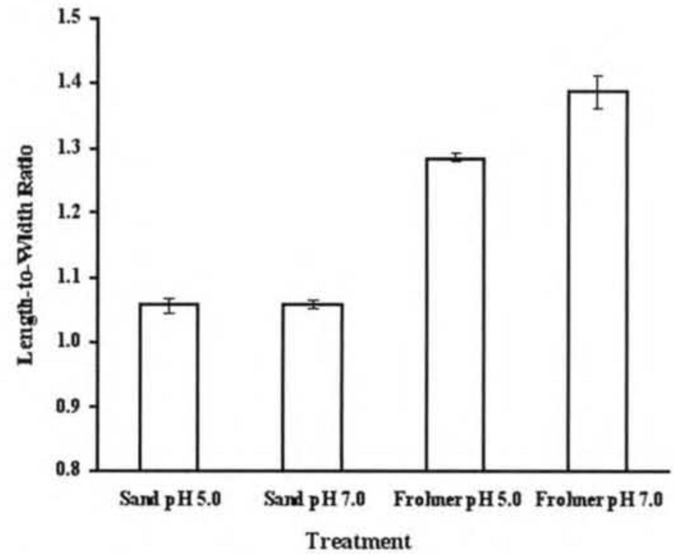

FIG. 1. The effects of substrate type (playground sand = sand; sediments from Frohner Meadows = Frohner) and pH on length-to-width ratios of nucleic DNA clusters. Clusters with the largest length-to-width ratios have the longest "comet" tails.

Our field and laboratory results suggest that mining effluent from the Nellie Grant Mine had both lethal and sub-lethal effects on Western Toad tadpoles. Tadpole survivorship and mass were lower when tadpoles were subjected to sediments from the site. Furthermore, our comet assay revealed a genotoxic effect for tadpoles exposed to the sediments. The length-to-width ratios of nucleic DNA clusters were larger for tadpoles exposed to the mining sediments than for tadpoles exposed to a control substrate, suggesting that DNA fragmentation was more severe for treatment tadpoles than for controls.

TABLE 1. The effects of substrate type and pH on the proportion of tadpoles surviving (survivorship), the average mass of surviving tadpoles (mass), and length-to-width ratios of DNA clusters (l/w ratio). (ANOVA).

Variable	Factor	Df	MS effect	F	p
Survivorship					
	Sediment	18	0.844	14.78	0.001
	pH	18	0.150	2.64	0.099
	Sediment x pH	18	0.084	1.47	0.257
Mass					
	Sediment	18	0.230	43.86	<0.001
	pH	18	0.006	1.08	0.361
	Sediment x pH	18	<0.001	0.14	0.867
L/W Ratio					
	Sediment	19	0.440	316.49	<0.001
	pH	19	0.016	11.33	0.003
	Sediment x pH	19	0.014	9.94	0.005

In the laboratory, pH had no significant effect on tadpole survivorship or mass. However, DNA fragmentation (indicated by larger length-to-width ratios) was higher at a pH of 7.0 than at 5.0 for tadpoles reared over sediment from Frohner Meadows. We do not know why DNA fragmentation was more severe at the higher pH. In laboratory conditions, heavy metals typically are more soluble in acidic conditions (Kotz and Treichel 1996) and should therefore have a more toxic effect at a lower pH. However, the composite nature of soil, with both organic and inorganic components, can create several buffering systems with complex ion formation and several equilibrium states (Harris 1999). Therefore, the unique composition of the effluent from the Nellie Grant Mine could cause some toxic elements to be more soluble at a higher pH.

Toxic sediments do not come solely from aban-

doned mine sites. In the Great Smoky Mountains National Park, runoff from roadsides and culverts contaminated streams and eliminated two stream breeding salamander species (Huckabee et al. 1975; Kucken et al. 1994). Two other amphibian species exhibited a 50% reduction in population size. Road construction had used fill from the Anakeestra rock formation containing significant levels of heavy metals.

Our results suggest that the comet assay is effective in assessing the toxicity of sediment effluent. As with organic pollutants (Clements et al. 1997; Ralph et al. 1996; Ralph and Petras 1997, 1998a,b), tadpoles *in situ* (caged for short time periods) or exposed to sediments in the laboratory could be used for bioassays. This technique would allow rapid assessment of contaminated sites and aid in reclamation decisions.

Acknowledgments.—We thank Mike Shevlin, Jon Griffin, Laura Peila, and Nichole Farr for helping with aquarium maintenance and other laboratory assistance. We also thank John Addis for his help with laboratory procedures. Our research was conducted with permission from authorities of the Helena National Forest and with appropriate federal and state collecting permits. Both laboratory and field experiments followed Carroll College and SSAR animal care guidelines. This project was funded with a Life Science Grant for Undergraduate Research from the Murdock Foundation.

Artwork and Slides Wanted for *HR*

We are always interested in obtaining illustrations of herpetological subjects for publication in *Herpetological Review*. Generally, original drawings should be of a scale that would permit reduction to fit a 90-mm wide column. Original art, or high quality photocopies, should be packaged to ensure safe delivery and sent to the Editor. Alternatively, we would be pleased to receive material in electronic format; consult the Editor for appropriate file formats and sizes.

Also, we are interested in evaluating outstanding color slides of amphibians and reptiles for possible use on future *HR* covers. When reviewing material for submission, photographers should keep in mind the vertical format of our covers. In addition to highlighting outstanding photography, our cover subjects should lend themselves to communication of biologically interesting information through accompanying text. If you would like to have your work considered, please contact the Editor ***prior*** to sending any slides. We prefer to review images as JPEG or PDF files before requesting examination of original slides. Postal and e-mail addresses are listed on the inside front cover.

HERPETOLOGICAL HUSBANDRY

Herpetological Review, 2005, 36(2), 156–157.

Evidence of Sexual Dimorphism in Neonate Henkel's Leaf-tailed Gecko, *Uroplatus henkeli*

SEAN C. FOLEY
and
SCOTT PFAFF
Department of Herpetology, Riverbanks Zoo and Garden
500 Wildlife Parkway, Columbia, South Carolina 29210, USA
e-mail (SCF): sfoley@riverbanks.org
e-mail (SP): spfaff@riverbanks.org

Uroplatus henkeli is one of eleven recognized species of *Uroplatus* endemic to Madagascar. The sex of all species of *Uroplatus* can easily be determined by the presence of large hemipenial bulges in adult males. In addition, adult *U. henkeli* are sexually dimorphic by color (Glaw and Vences 1994; Henkel and Schmidt 1995). It has also been noted that some male *U. henkeli* exhibit a vertebral stripe as neonates; however, many juvenile males do not manifest this trait (Foley and McGinnity 1996). Other than the occasional presence of a vertebral stripe, sexual dimorphism in juvenile *U. henkeli* has yet to be described.

At Riverbanks Zoo and Gardens, two other traits have been consistently noted in neonates: parallel, longitudinally-oriented black striations on the dorsum and a transverse, bilaterally symmetrical black mark at the base of the skull. In a group of ca. 30 *U. henkeli* that were reared from hatching to sexual maturity, these two traits were never observed on the same neonate and seemed to correlate with the sex of the gecko. The presence of the markings was thought to represent a reliable method of determining the sex of neonate *U. henkeli*.

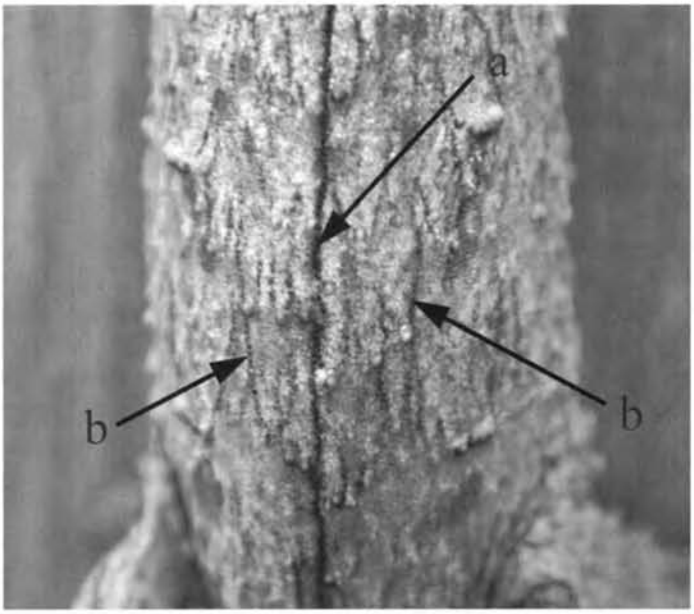

FIG. 1. Male neonate *Uroplatus henkeli* displaying the typical: (a) vertebral stripe and (b) dorsal striations.

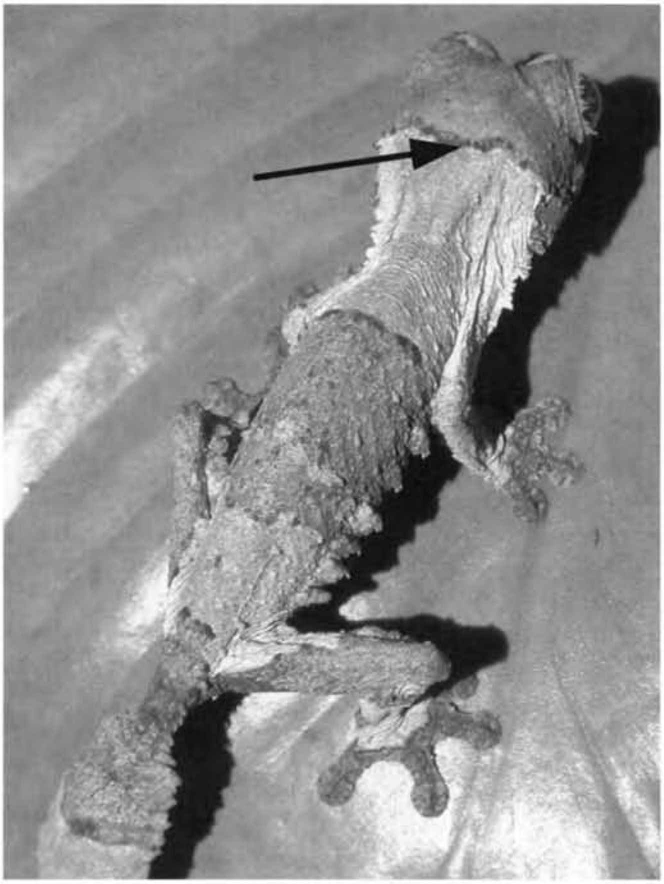

FIG. 2. Female neonate *Uroplatus henkeli* displaying the typical transverse, bilaterally symmetrical black marking at the base of the skull.

To test this hypothesis, 100 hatchling *U. henkeli*, from twelve different bloodlines, were selected for rearing. Of those, 50 exhibited the parallel black striations on the dorsum and were thought to be males, including two that also exhibited the cranial marking (Fig. 1). The other 50 did not exhibit the dorsal striations and were thought to be females. Forty-five of these females also exhibited the black cranial mark at the base of the skull (Fig. 2). All of the neonates were reared until adult external sexual characteristics began to appear (i.e., hemipenial bulges and larger spur size in males), which can take up to nine months to manifest.

The most accurate period to sex neonates was directly after they hatched. During this time the visual characteristics were very apparent. As the geckos grew, these traits often faded and in many cases disappeared altogether. The fading or disappearance of these traits was unique to each gecko and occurred in as little as three months while others retained the markings into adulthood. Also, because of *U. henkeli*'s ability to change color, the markings may not be easily distinguishable, especially during the daylight hours when the markings and ground color tend to lighten. At night, there is significantly more contrast between the markings and the ground color.

According to our observations, the only characteristic that was 100% effective in sexing neonate *U. henkeli* was the presence of the black striations on the dorsum of males. All males exhibited this trait while none of the females did. The presence of a vertebral stripe (Fig. 1) also suggested that an individual would be a male but was only present in 38% of males sampled (Table 1).

TABLE 1. Presence of physical characteristics in male and female *Uroplatus henkeli*.

Sex	N	Vertebral stripe	Dorsal striations	Cranial markings
Male	50	19 (38.0%)	50 (100%)	2 (4.0%)
Female	50	0	0	45 (90.0%)

The horizontal black marking on the cranium (Fig. 2) was observed in 90% of the females and 4% of the males (Table 1). Thus our data are strongly suggestive of juvenile sexual dimorphism in *Uroplatus henkeli*.

Acknowledgments.—We thank Keith Benson, Orinna Clark, and Jim Clark for their helpful comments with the text.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 36, Number 1 (March 2005).

CAUDATA

ENSATINA ESCHSCHOLTZII OREGONENSIS* x *PICTA (Oregon x Painted Salamander Intergrade). **BEHAVIOR.** *Ensatina eschscholtzii* is the most widespread and common plethodontid salamander in western North America, with the range extending from southern British Columbia to northern Baja California (Stebbins 1985. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 336 pp.). However, little is known about the climbing behavior of this salamander. In addition, little is known about the climbing behavior of *Batrachoseps attenuatus* or *Taricha granulosa* (Hayes and Hayes 2003. Herpetol. Rev. 34:45–46; Aubry 2000. J. Wildl. Mgmt. 64:1041–1052; Jones and Aubry 1985. Herpetol. Rev. 16:26; Stebbins 1954. Univ. California Publ. Zool. 54:47–124).

An extended period of observation of the climbing behavior of terrestrial salamanders and their use of stumps as habitat was performed from 23 Nov 2001 to 29 Mar 2003. The site is located within the coastal redwood region of Humboldt County, in a semi-rural area of Westhaven, California USA (T8N R1E SW1/4 Sec 31; elev. ca. 100 m) (Sundell and Norman 2003. Herpetol. Rev 33:4). The stumps were Redwood (*Sequoia sempervirens*) that were logged five decades ago. The forest canopy consisted of old-growth Sitka Spruce and second growth Redwood, with few Red Alder (*Alnus rubra*) and Cascara Buckthorn (*Rhamnus purshiana*) in the understory.

On 29 Jan 2001, two subadult female *E. eschscholtzii* intergrades were found on a Redwood stump (stump #1) covered with introduced English Ivy (*Hedera helix*) under a piece of Redwood bark in site 5. The stump was 6 m diam with Evergreen Huckleberry (*Vaccinium ovatum*) and spruce seedlings present on top of the stump ca. 1 m off the ground. The cover object measured 30 x 20 x 4 cm with a temperature of 11.4°C in the covered litter and English Ivy roots. The first female measured 7.3 cm TL and 3.6 cm SVL (measured to the anterior edge of cloaca), the other female measured 7.6 cm TL and 3.9 cm. SVL

On 16 Feb 2002, an *E. eschscholtzii* adult male intergrade (10.4 cm TL, 4.6 cm SVL) and a *B. attenuatus* were found 1.2 m off the ground on another redwood stump (stump #2), under litter, which was 8°C measured at a depth of 9 cm. The stump measured 5.2 m diam and was covered by False Lily-of-the-Valley (*Maianthemum dilatatum*) and two young spruce trees, which measured 4 cm in diameter.

On 2 Mar 2002, an adult male *E. eschscholtzii* intergrade (9.3 cm TL, 4.5 cm SVL) was found under litter on stump #2. This male was marked as LF2 RF2. The litter temperature was 7.3°C, which was measured at a depth of 9 cm. In addition, springtails, centipedes, and arachnids were located in the litter.

On 16 Mar 2002, an adult female, *E. eschscholtzii* (10.5 cm TL, 5.1 cm SVL) was found on another redwood stump (#3), 4.5 m diam. This salamander was wedged between pieces of outer bark, located 1.6 m off the ground.

The first stump was inspected again on 6 April 2002, and produced a female Rough Skinned-Newt (*Taricha granulosa*) (11.7 cm. TL, 4.7 cm SVL). The newt was found under the same piece of bark as the previous Ensatina salamanders found on top of stump #1. Also, present under the cover object with the newt was an adult *B. attenuatus*, which escaped capture.

On 16 Nov 2002, a subadult female *E. eschscholtzii* (7.6 cm TL, 4.1 cm SVL), was found under litter on stump #2, with a litter temperature of 10.8°C. Then again, on 25 Jan 2003, an adult male *E. eschscholtzii* (9.6 cm TL, 5.0 cm SVL), was found on the same stump, with a litter temp of 13.0°C. However, this was a recapture of the adult male (LF2RF2), first captured on 2 Mar 2002, on the same stump #2. Again, three more *B. attenuatus* juveniles were located under litter on top of the same stump. The litter had a temperature of 9.8°C at a depth of 9 cm.

On 15 Mar 2003, a subadult Wandering Salamander (*Aneides vagrans*) (7.4 cm TL, 4.1 cm SVL) was located on a Redwood stump (stump #4) with a subadult *B. attenuatus* (7.2 cm TL, 3.2 cm SVL), under a Redwood cover object 78 cm x 40 cm x 28 cm, which was located 1.5 m. above the forest floor. Stump #4 measured 3.1 m diam. The temperature in the interstitial space was 12.0°C.

Finally, on 29 Mar 2003, three more subadult *B. attenuatus* were located under litter on top of stump #2, which had a litter temperature of 11.7°C covering the coiled salamanders.

These observations emphasize the colonization of tree stumps

Herpetological Review

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

Society for the Study of Amphibians and Reptiles

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

Annual Dues and Subscriptions: Annual membership dues for the year 2005 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with Visa or MasterCard (account number and expiration date must be provided). Payment should be sent to: Theodora Pinou, SSAR Treasurer, Department of Biological & Environmental Sciences, Western Connecticut State University, 181 White Street, Danbury, Connecticut 06810, USA. Fax: (203) 837-8769; e-mail: PinouT@wcsu.edu.

Future Annual Meetings

2005 — University of South Florida, Tampa, Florida, 6–11 July (with ASIH, HL)
2006 — New Orleans, Louisiana, 12–17 July (with ASIH, HL)

About Our Cover: *Siphlophis compressus*

Liana snakes are slender, usually under a meter in length and include six species: *Siphlophis cervinus*, *S. compressus*, *S. leucocephalus*, *S. longicaudatus*, *S. pulcher*, and *S. worontzowi* (Peters and Donoso-Barros 1970. Catalogue of the Neotropical Squamata. Part 1. Snakes. Washington, D.C., 347 pp.; Zaher and Prudente 1999. Journal of Herpetology 33:698–702). *Siphlophis compressus* was formerly placed in the monotypic genus *Tripanurgos*, but was reassigned to *Siphlophis* owing to its hemipenial morphology (Zaher and Prudente 1999, *op. cit.*; Zaher and Prudente 2003. Herpetological Review 34:304–307). The genus is distributed from Costa Rica and Trinidad south to Bolivia and tropical Brazil. Four species are Brazilian endemics, with *S. cervinus* and *S. compressus* ranging throughout the Amazon Basin and Trinidad northwest to Panama and Costa Rica, respectively.

Like its congeners, the Red-eyed Liana Snake, *S. compressus*, is nocturnal and arboreal. The preferred habitat is lowland rainforest, usually in humid locales, and often in flooded forest. Reaching at least 150 cm in length, *S. compressus* may be the largest member of the genus (Cunha and Nascimento 1978. Ofidíos da Amazônia 10. As cobras de região leste do Pará. Publicações Avulsas 31. Museu Paraense Emílio Goeldi, Belém, 218 pp.). This species has been known to consume small mammals (Q. Dwyer, personal communication), but it is primarily a lizard specialist, preying on everything from *Alopoglossus*, *Neusticurus*, *Norops*, and *Gonatodes* to larger species such as *Ameiva*, *Kentropyx*, *Enyalioides*, and even *Corytophanes* (crest and all!) (Cunha and Nascimento 1993. Boletim do Museu Paraense Emílio Goeldi 9:1–191; Martins and Oliveira 1998. Herpetological Natural History 6:78–150; Medem 1969 [dated 1968]. Revista de la Academia Colombiana de Ciencias Exactas, Físicas y Naturales 13:149–199). Prey is captured by active foraging, both in trees and on the ground. They are egg layers and the hatchlings bear a conspicuous cream-colored parietal ring, much like hatchlings of some *Leptodeira* species. The ring may be retained into adulthood, as is typical of northern populations, or obliterated by the reddish ground color.

The cover photo depicts an adult female *Siphlophis compressus*, 83.3 cm long. It was found at night while it climbed in a small tree about 3 m above the forest floor at Finca El Naranjal, Golfito, Puntarenas, Costa Rica. The site is near sea-level and about half a kilometer from the Pacific coast. The snake was captured in the month of January, the height of the dry season, and the usually humid forest was parched.

PHOTO BY ROB EAGLESTON

The photograph was taken by **Louis W. Porras**. He used a Canon AT-1 camera, Canon 100mm f/4 lens, and Fujichrome Velvia ISO 50 film exposed at f/11. Lighting was obtained using a Norman P400D power pack with 2 LH2 lamp heads and umbrellas.

Porras is proprietor of Eagle Mountain Publishing, LC, in Eagle Mountain, Utah. A veteran of numerous field trips to Mexico, the Caribbean, Central and South America, Louis now dedicates his efforts to studying the herpetofauna of the Neotropics and the Intermountain West and publishing.

SSAR BUSINESS

Announcing the 2005 Joint Meeting of Ichthyologists and Herpetologists 6–11 July 2005

The annual meeting of the Society for the Study of Amphibians and Reptiles, The Herpetologists' League, and the American Society of Ichthyologists and Herpetologists will be held 6–11 July 2005, hosted by the University of South Florida at the Marriott Tampa Waterside Hotel and Marina, Tampa, Florida. Please refer to the Joint Meeting website <http://www.dce.ksu.edu/jointmeeting/> for information on how to register for the meeting. All material typically included in the Call for Papers is now accessible on the website.

SSAR Election Results

Results of the 2004 SSAR election are as follows:

President-Elect: .... Roy McDiarmid

Secretary: .... Marion Preest

Treasurer: .... Theodora Pinou

Board Members (Class of 2008):

.... Rafe Brown, Meredith Mahoney

.... Jim McGuire, Richard Shine

Thanks to all of the nominees who agreed to stand for positions and to Maureen Kearney (Elector).

Kennedy Student Award Committee Annual Report, 2005

The Kennedy Award Committee (Craig Franklin, Mark Jordan, Terry Schwaner, Lynette Sievert, Robert Gatten, Jr., Chair) has completed its work for Volume 38 of the *Journal of Herpetology*. The Committee has selected "Using chorus-size ranks from call surveys to estimate reproductive activity of the wood frog (*Rana sylvatica*)" by **Cameron Stevens** (Cynthia Paszkowski, coauthor; Vol. 38:404–410). The Kennedy Award carries with it a cash prize of US $200 or the winner's selection of any SSAR publications valued at twice that amount. The Committee was impressed with the high quality of a number of eligible papers and would also like to acknowledge a runner up, **Caren Goldberg,** for her paper "Habitat use and spatial structure of a barking frog (*Eleutherodactylus augusti*) population in southeastern Arizona" (Cecil Schwalbe, coauthor; Vol. 38:305–312).

The committee invites all student members of the Society to submit their work to the *Journal*, and encourages regular members who supervise the work of students to draw this award to the attention of those students.

2005 Metter Award Winner

The Dean E. Metter Memorial Award was established to encourage students to pursue field research in herpetology and to facilitate field research by providing funds for related expenses. The Metter Award Committee is pleased to announce that this year's winner is Mr. Matthew W. H. Chatfield ("Hybrid zone dynamics between two species of salamanders in the genus *Plethodon*"). The committee (Joseph Beatty, Anne Maglia, and Brian Miller) was extremely impressed with all eight proposals but had to choose a single awardee.

Matthew Chatfield earned a B.A. in Biology from The University of Chicago and is now a Ph.D. student in the Department of Ecology and Evolutionary Biology at the University of Michigan working jointly with L. Lacey Knowles and Ronald A. Nussbaum. He has an impressive record working as a field biologist in a variety of ecological systems and with a broad spectrum of taxa. His PhD work is focusing on hybridization zones between *Plethodon jordani* and *P. metcalfi* and he is gathering data with the intent to understand more about the process of speciation as well as the maintenance of species boundaries between these two lungless salamanders.

NEWSNOTES

Kansas Herpetological Society Annual Meeting

The Kansas Herpetological Society held its 31st Annual Meeting at Kansas State University in Manhattan, Kansas, on November 6–7, 2004. Approximately 110 participants attended scientific paper sessions presented by scientists and students from across the nation. Featured speaker was Alicia Mathis, professor at Southwest Missouri State University in Springfield. Dr. Mathis spoke about salamander conservation.

Daphne Jones, a student at Emporia State University, received the 2004 Howard K. Gloyd/Edward H. Taylor Scholarship, honoring the memory of two great biologists with strong ties to Kansas. The 2004 Alan H. Kamb Grant for Research on Kansas Snakes were made to Erik Bartholomew, a student at Fort Hays State University. Dwight R. Platt, Bethel College, was recognized as the seventh recipient of "The Suzanne L. & Joseph T. Collins Award for Excellence in Kansas Herpetology."

In 2005, the Society will meet at Pittsburg State University in Pittsburg, Kansas.

Gopher Tortoise Council Grants

The J. Larry Landers Student Research Award is a Gopher Tortoise Council competitive grant program for undergraduate and graduate college students. Proposals can address research concerning gopher tortoise biology or any other relevant aspect of upland habitat conservation and management. The amount of the award is variable, but has averaged $1,000.00 over the last few years.

The proposal should be limited to four pages in length and should include a description of the project, a concise budget, and a brief resume of the student. Proposals should be submitted by 31 August 2005 to: Bob Herrington, Chair of Research Advisory Committee, Georgia Southwestern State University, Department of Biology, Americus, Georgia 31709, USA; e-mail: bherring@canes.gsw.edu.

Check List—A New Online Journal

Check List is a scientific journal devoted to publish species lists and geographic distribution maps of any taxa. We are all aware, these days, that the effort to preserve natural remnants of species ranges is fundamental for the perpetuation of life as it has evolved. The first step to accomplish this is to record species occurrences in those remnants and adjacent areas. This sort of study has been neglected for being considered "too basic" or "not directly applied." *Check List* was therefore created to fill this gap in publishing papers on such important inventories. *Check List* is available at: http://www.rc.unesp.br/ib/checklist/index.htm.

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

6–11 July 2005—48th Annual Meeting, Society for the Study of Amphibians and Reptiles, together with The Herpetologists' League and the American Society of Ichthyologists and Herpetologists. University of South Florida, Tampa (USA). Information: http://www.dce.ksu.edu/jointmeeting/.

27–30 July 2005—29th Annual International Herpetological Symposium, Scottsdale, Arizona (USA). Information: www.kingsnake.com/ihs.

15–19 August 2005—VII Latin American Congress of Herpetology, Universidad Autónoma del Estado de Morelos, Cuernavaca, Morelos, México. Information: http://www.ibiologia.unam.mx/barra/congresos/frame.htm.

21–23 October 2005—Snakebites Symposium, University of Nebraska Medical Center, Omaha, Nebraska, USA. Information: http://app1.unmc.edu/cce/snakebites/.

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure

that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **María del Rosario Castañeda** or **Michele Johnson**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

First Plethodontid Salamander from Asia

The Plethodontids comprise almost 70% of the known salamander species, with nearly all of these confined to North and Middle America. A small number of species occur in southern Europe, and this enormous distributional gap has long vexed biogeographers. The exciting discovery of a plethodontid in southwestern Korea helps fill the gap, and suggests that the Plethodontidae was formerly more widespread in the Holartic region. A new genus (*Karsenia*) is erected to accommodate the new species (*K. koreana*), which is now known from 16 localities in three provinces. Bayesian analysis of 1503 base pairs of the nuclear gene *Rag-1* demonstrates that the new taxon is clearly a plethodontid, nested within a clade that includes the desmognathines and *Aneides*, but otherwise widely diverged from other members of this group. The authors propose that other species of plethodontids await discovery in the region between the Korean Peninsula and the southwestern Mediterranean.

Min, M. S., S. Y. Yang, R. M. Bonett, D. R. Vietes, R. A. Brandon, and D. B. Wake. 2005. Discovery of the first Asian plethodontid salamander. Nature 435:87–90.

Estimating Consistency In Fossil Calibration Points: Turtles As An Example

Heterogeneity in DNA substitution rates and inaccuracy in fossil age estimations have been two major problems when estimating clade divergence times. Additionally, the utilization of one fossil as a single calibration point has been highly criticized because it can increase potential bias when age estimation is not accurate. The authors propose a strategy to identify inconsistent fossil age estimations when multiple calibration points are available. The method measures consistency (or agreement) between fossil and molecular age estimates using each of the available fossil calibration points independently. The phylogeny of turtles was used as an example to test the method. Bayesian and Parsimony analyses were performed using cytochrome *b* (cyt*b*), nuclear recombination activating gene 1 (RAG-1) and R35 intron sequences of 23 species—representing all major lineages of living turtles. Seventeen available fossils were placed in the molecular phylogeny using a parsimony analysis of 115 morphological characters as a guide. Penalized likelihood was used to estimate divergence times in the molecular phylogeny. Results indicated that seven of the seventeen calibration points were inconsistent and were therefore eliminated from the analysis. The authors indicate that the magnitude of the effect of calibration inaccuracy depends on tree topology, inferred branch lengths and the proximity of the estimated node with the inconsistent fossils. This method promotes the removal of inaccurate calibration points to reduce the variance on time estimations.

Near, T. J., P. A. Meylan, and H. B. Shaffer. 2005. Assessing concordance of fossil calibration points in molecular clock studies: an example using turtles. The American Naturalist 165:137–146.

Historical Fragmentation Or Recent Population Decline In New Zealand Rare Skinks

To clarify whether the disjunct distribution and small population sizes of *Oligosoma grande* skinks in New Zealand are the result of a recent decline due to anthropogenic factors or to historical pre-human climatic changes, the authors sequenced the hypervariable region I (HVRI) of the mitochondrial control region and 12 nuclear microsatellites of 65 individuals, representing most known populations. Analyses included: 1) parsimony and maximum likelihood phylogenetic reconstructions, 2) calculation of F_{ST} for all pairwise population comparisons and 3) estimation of the effective population size through the genetic diversity parameter q. Results demonstrated that both Western and Eastern populations are highly structured genetically, indicating minor inter-population dispersal. Eastern populations showed high mitochondrial diversity despite their small sizes, which suggests that current populations are a fraction of their historical sizes, indicating a recent decline. On the contrary, Western populations had low levels of genetic diversity, evidence of a possible population bottleneck or a founding event. In conclusion, high levels of genetic structure more likely indicate that the distribution of *Oligosoma grande* skinks was discontinuous: Western and Eastern populations most probably have independent evolutionary histories that predate human arrival in New Zealand. However, small population sizes, additional population declines and evidence of the limited ability to recolonize new habitats indicate the necessity of prompt conservation strategies to prevent *O. grande* extinction.

Bright Pattern, But Not Bright Color, As Requirement For Aposematism

Aposematism, the use of bright colors and patterns to advertise noxiousness, has been reported commonly in nature. However, bright coloration might also have costs, as it may act to warn specialized predators (that can handle noxious components) and alert potential prey. In theory, the use of patterns and colors that do not

interfere with crypsis, but provide a characteristic and recognizable signal, would be an alternative strategy to combine cryptic and aposematic signals. Many viperids are venomous, cryptic, sit-and-wait predators that show a very distinctive dorsal pattern. The authors used plastiline models with typical *Viper berus* zigzag patterns to test if the coloration pattern provides a dual function of crypsis and aposematism. To account for the effect of crypsis, models were placed against both white cards and natural backgrounds and to account for aposematic signals, half of the models had zigzag patterns and half lacked them. Marks of avian predators on the models and their relative location on the snakes' bodies were recorded. Binary logistic regression identified pattern and background as significant predictors of attack, showing that models with a zigzag pattern were attacked less frequently than models without it and models on the white board were attacked less frequently than models on a natural background. Models with zigzag patterns were attacked mainly in the anterior quarter of the body, while plain models attacks were scattered along the body, suggesting the recognition of a warning pattern by predators. Results support that zigzag patterns in *Viper berus* accomplish both the role of crypsis and warning coloration, evidencing that bright conspicuous coloration is not a prerequisite for predatory avoidance, a classic assumption in aposematic theory.

Disruption Of Endocrine Function Linked To Amphibian Population Declines

Population declines in amphibians have been detected worldwide, although for many species causes are still unclear. *Acris crepitans* is a native species of the northeastern half of the United States that has shown population declines in the past 25 years. Industrial compounds and their by-products have been associated with amphibian declines; polycyclic aromatic hydrocarbons (PAHs), polychlorinated byphenils (PCBs), polychlorinated dibenzofurans (PCDFs), and polychlorinated dibenzo-*p*-dioxins (PCDDs) have been linked with disruption in endocrine function, and DDT (p,p-dichlorophenyl trichloroethane) and the herbicide atrazine have been associated with biased functional sex ratios, reduced size at metamorphosis and delayed maturation among amphibians. To test the relationship between population declines and occurrence of intersexuality (hermaphrodism) of *Acris crepitans*, the authors examined museum specimens collected between 1852 and 2001 in Illinois, and determined proportions of male, female and intersex individuals. Three regions were delimited (northeast, central and southern), based on human population densities and agricultural intensity, and five time periods were considered based on industrial pollutants utilization. Results show that the proportion of intersex individuals was much larger and the proportion of females smaller in the northeast Chicago area, where the highest human population density and intensive industry occurs. The southern region, with the least intensive agriculture and industry, had the smallest proportion of intersex individuals. From 1930 to 1945 the percentage of intersex individuals increased until its peak in the 1946–1959 period, a rise accompanied by a reduction in female proportion, and a strong correlation with PCB's intensive use and the introduction of DDT. This study evidences a relation between endocrine disruption (intersexuality) and *Acris crepitans* population declines, suggesting the increase of PAHs, PCBs, PCDFs, PCDDs, and DDT usage as a contributing factor.

Correlation Between Ontogenetic Changes In Coloration And Behavioral Changes

Color pattern is known to affect antipredatory behavior in snakes. In particular, disruptive patterns effectively conceal individuals when immobile, and striped, finely speckled and uniform patterns confound predators when the snake is in motion. Some species experience ontogenetic changes in their coloration patterns, but corresponding changes in behavior, although suspected, have not been investigated. The author studied behavioral responses to predator attacks in *Coluber constrictor* snakes, where juveniles have a blotched (disruptive) pattern and adults have a solid coloration. Results show that hatchlings were more prone to respond with an aggressive behavior when confronted by a predator, while adults where more likely to flee. Additionally, sprint speed was not significantly different between hatchlings and adults when accounting for the effects of size. However, sprint speed was correlated with body length, with adults faster than hatchlings on an absolute scale. In conclusion, this study supports the hypothesis that in *Coluber constrictor* there is a correlation between color pattern and antipredator behavior, which provides effective alternative defense strategies at different life stages.

Creer, D. A. 2005. Correlations between ontogenetic change in color pattern and antipredator behavior in the racer, *Coluber constrictor*. Ethology 111:287–300.

Evolution Of Viviparity And The Cold-Climate Hypothesis

The cold-climate model states that viviparity evolved as an adaptation to cold climates, which are associated with high altitudes and latitudes. This hypothesis is supported by the characteristic lower temperatures in high altitudes and latitudes and, within

squamates, by 1) a large proportion of viviparous species living in high altitudes and latitudes, and 2) the association of recent origins of viviparity with recent invasions of higher altitudes and latitudes. The author tested, within a phylogenetic context, whether mode of reproduction was correlated with altitude and latitude in *Phrynosoma* lizards. Reproductive modes at minimum, midpoint, and maximum altitudes and latitudes were compiled for all species of *Phrynosoma* from literature, museum specimens, and field observations. Hodges and Zamudio's (2004) phylogeny, based on molecular and morphological characters, was used as the context for analyses. Results documented no correlation between latitude and reproductive mode; however, minimum and midpoint altitude were correlated with viviparity. This suggests that, in the cold-climate hypothesis context, altitude might be a better predictor of cold climates than latitude. Or, instead of an indicator of cold climate, altitude may incorporate other selective forces important for the evolution of viviparity, such as oxygen content, humidity conditions, daily temperature fluctuations, and growing season length.

HODGES, W. L. 2004. Evolution of viviparity in horned lizards (*Phrynosoma*): testing the cold-climate hypothesis. Journal of Evolutionary Biology 17:1230–1237.

Phylogeny And Colonization History Of Neartic *Bufo*

Three different colonization hypotheses have been proposed for the origin of the Neartic *Bufo*, suggesting the group is: 1) polyphyletic, resulting from different colonizations from Africa, 2) paraphyletic, resulting from a single colonization from South America and subsequent colonization into Eurasia, or 3) monophyletic, derived from the Neotropics. The authors sequenced ~ 2500 bp of the 12S, 16S, and intervening valine tRNA mitochondrial genes from 56 species, including South American, Eurasian, African, and most Neartic representatives. Parsimony, maximum likelihood and Bayesian analyses were performed to reconstruct phylogeny, and parametric bootstraping was used to test the different hypotheses for *Bufo* Neartic colonization. Although different optimality criteria rendered slightly different relationships within *Bufo*, all strongly supported the monophyly of the Neartic *Bufo* clade, with disagreements regarding its sister taxon (either a *Bufo marinus* clade or a Middle America *Bufo* clade). Furthermore, parametric bootstrap analyses rejected the polyphyly, paraphyly and non-monophyly hypotheses, strongly corroborating the monophyletic Neartic *Bufo* hypothesis. Results suggest that the Neartic *Bufo* evolved from a northward radiation from a South American ancestor, without any subsequent intercontinental dispersal into Eurasia. Additionally, the authors discuss evidence suggesting that North American *Bufo* colonization occurred prior to the development of a Central American Land Bridge, providing support for a transmarine dispersal hypothesis.

PAULY, G. B., D. M. HILLIS, AND D. C. CANNATELLA. 2005. The history of a Neartic colonization: molecular phylogenetics and biogeography of the Neartic toads (*Bufo*). Evolution 58:2517–2535.

Effects Of Destructive Collecting Practices On Reptile Abundance

Herpetofauna collection practices frequently result in permanent habitat damage; these consequences have increased in recent years, due to the rising demand for supplying the pet trade market. Practices include breaking apart and overturning rocks to expose hiding reptiles. The authors quantified the effects of destructive collecting techniques on reptiles by comparing abundance before and after disturbance on rock outcrops in Arizona. Additionally, in disturbed sites, individual location was quantified: whether reptiles were on an original rock surface, a freshly exposed surface, or a rock that was moved in the manipulations. Abundance of lizards increased in both control and treatment sites after the disturbance, with the increase larger in control sites. The effect of disturbance on abundance varied between seasons and species, and within species varied between seasons, sexes, and age-classes. Authors attributed interspecific variation to differences in reproductive ecology and habitat utilization. Results suggest that destructive collecting techniques led to a decrease in reptile abundance of diurnal lizards, and that portions of undisturbed rock outcrops were preferred. Based on the results, strict regulation of collecting methods is recommended, along with an increase in law enforcement to make restrictions effective.

Effect Of Paedomorphic Characters in Salamander Phylogeny

The significance of developmental characters in phylogenetic reconstruction has been controversial for decades. In salamanders, several lineages show paedomorphic characters, and it has been suggested they all evolved independently. However, if similar, large-scale developmental changes are present in distantly related lineages, phylogenetic reconstruction based only on adult morphology can be misleading; paedomorphic species will group together, based on the shared presence of larval (paedomorphic) traits. The authors added new morphological and molecular data to previously published salamander analyses to test the confounding effects of paedomorphic characters in morphology-based phylogenetic reconstruction. Parsimony and Bayesian analyses were performed including thirty-two species, representing all ten living families. Analyzed matrices included: 1) morphological data only, including and excluding paedomorphic characters; 2) molecular data only, including ribosomal and nuclear sequences, and 3) morphological and molecular data combined, with and without cod-

ing morphological adult characters as missing data for paedomorphic taxa and/or including or excluding paedomorphic characters. Both parsimony and Bayesian analyses of the morphological-data matrices recovered three of the four paedomorphic families as monophyletic. These results are contradicted by the molecular and combined analyses, suggesting that the placement of the paedomorphic families as a single clade reflects the influence of paedomorphic characters and not phylogenetic history. The authors discuss different factors that could lead to an incorrect placement of paedomorphic taxa and propose a robust phylogenetic hypothesis for salamanders.

ZOO VIEW

Free Power Point Presentations

When I arrived in Washington, D.C. about a decade ago, one of the first things I did was to go to the Smithsonian Institution's National Museum of Natural History to examine the splendid collection of herpetological books and other printed materials. Of particular interest was the Joseph F. Cullman 3rd Library of Natural History (in SI Special Collections Department) which houses books written no later than 1840. As an example, in 1497 a woodcut showing a "gamaleon" was published in a body of works called "Hortus sanitatis" [Garden of Health]; the creature looks more like a canine with wings than a chameleon (Fig. 1). Librarians Leslie Overstreet and Daria Wingreen spent many hours finding historical illustrations of herps like these for me to covet. In addition, Kirsten van der Veen from the SI Dibner Library of the History of Science & Technology and National Zoological Park Librarian Alvin Hutchinson checked many sources for illustrations. Roy McDiarmid's personal library in the museum was also a treasure trove and he kindly let me scan many of his books.

FIG. 1. Gamaleon or chameleon from body of works called "Hortus sanitatis" [Garden of Health] in 1497. Quote is loose translation from text of early English version: "Chameleon is a beste with ii wynges and four fete havinge an hede lyke an adder and a longe wronge tayle lyke a dragon and bereth gere [hair?] on his backe lyke woll and the clothe that therof is made can nat burne." Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

It occurred to me that seeing these original tomes was a unique opportunity, largely unavailable to other herpetologists. The Smithsonian's collection is unrivaled in breadth and depth. As a result, I asked Martin Kalfatovic, Permissions Coordinator from the SI Libraries, if it would be possible to duplicate these images to create a series of ***free*** power point presentations for zoo meetings, regional herp societies, natural history organizations, academics teaching herpetology, and others within the biological community and he assisted me in doing so. Here are the ones currently available, mostly using materials from the SI collection:

1) ***Herpetological Time Travel Through the Zoo and Aquarium World***
Divided into three parts—Deceased zoo herpetologists, historical vignettes, and tour of reptile buildings and aquaria throughout the world. Uses many historical illustrations and photos, often provided by zoo colleagues. Topics include first reptile building (Tower of London in 13th century), first zoo snakebite fatality, studies on brooding pythons in zoos beginning at Menagerie Jardin des Plantes in 1841, studies and experiments on fear of snakes at London Zoo by Charles Darwin, public outcry over feeding live food to snakes at London Zoo in 1860s (an issue so contentious that it was debated in Parliament), collection of Galapagos tortoises by Charles Townsend, final days of the Belle Vue herpetological collection, and others.

2) ***Are Komodo Dragons Really More Intelligent than Other Reptiles?***
Divided into four parts: historical studies on varanids, books on varanids, history of dragons in zoos, and play behaviors in a dragon at Smithsonian National Zoo. Produced with Trooper Walsh and Claudio Ciofi.

3) ***Chameleons: Biology and Captive Management***
Divided into four parts: biology, history of chameleon illustrations, captive history, and our research trip to Madagascar to study panther chameleons. Produced with Gary W. Ferguson.

4) ***How to Draw a Chameleon?***
Five centuries of chameleon illustrations showing evolution of this art and portraits of influential chameleon biologists. Produced with Gary W. Ferguson.

5) ***Zoo Herpetology. The Past to Now***
Suggestions for future herpetological research in zoos.

6) ***Betwixt Plated Decks. Five Centuries of Turtle Illustrations***
Five centuries of turtle illustrations and portraits of influential chelonian biologists.

7) ***The Art of Drawing Serpents***
Twelve centuries of snake illustrations from scientific and semi-popular works and portraits of influential snake biologists.

8) The Nature of Crocodilians Depicted Through Art and Literature
Twelve centuries of crocodilian illustrations showing examples from scientific and semi-popular works. Also includes books on crocodilians and portraits of influential crocodilian biologists.

9) Going, Going, Gone? The Case of Disappearing Frogs and Toads
Six centuries of frog and toad illustrations and a discussion of the role and mission of the Declining Amphibian Populations Task Force.

These CDs are available ***free*** for one-time use. Presentations last between 45–60 min, with accompanying background music. They cannot be duplicated or distributed and must be returned to me.

For additional information, contact me at <jbmurphy2@juno.com>. *Mailing Address*: 3100 Connecticut Ave., N. W., Apt. 431, Washington DC 20008, USA.

Kevin R Buley, Curator of Lower Vertebrates & Invertebrates at Chester Zoo, is editor of the new "Shellshocking News," official newsletter of the European Association of Zoos and Aquariums (EAZA). The newsletter details the activities of the organization's Turtle & Tortoise Campaign 2004/2005. The EAZA has 294 member zoos and aquaria; the mission of this campaign is to conserve chelonians through captive breeding initia-

tives and *in situ* conservation projects. Kevin is soliciting articles, photographs, ideas, and suggestions for the next issue. To send materials or be added to the electronic mailing list, contact him at Chester Zoo, Upton-by-Chester, Chester CH2 1LH, United Kingdom, (Direct Telephone Line: +44 1244 389402, Direct Fax: +44 1244 381352, e-mail: *k.buley@chesterzoo.org*, Website: *www.chesterzoo.org*).

Dr. Joseph Mendelson is the new herpetological curator at Zoo Atlanta. I first met him and his new boss, general curator Dr. Dwight Lawson, when they were lowly graduate students laboring under Jonathan Campbell at University of Texas at Arlington. Later, Joe received his PhD in Systematics and Ecology (Herpetology) at University of Kansas. After graduation, he was a professor of biology at Utah State University. Dwight and Joe will make a formidable team at Zoo Atlanta as both have a broad grasp of herpetology, have been involved in many field projects throughout the world, and have published extensively.

Clay Garrett from the Fort Worth Zoo analyzes the potential value of zoo collections for significant research in herpetology and opportunities for their caretakers by stressing the need for academic-zoo collaborations in the following article. Of particular interest are the new SSAR web pages being developed by the Relationships with Herpetologists at Zoological Parks Committee in 2005.

— *James B. Murphy, Section Editor*

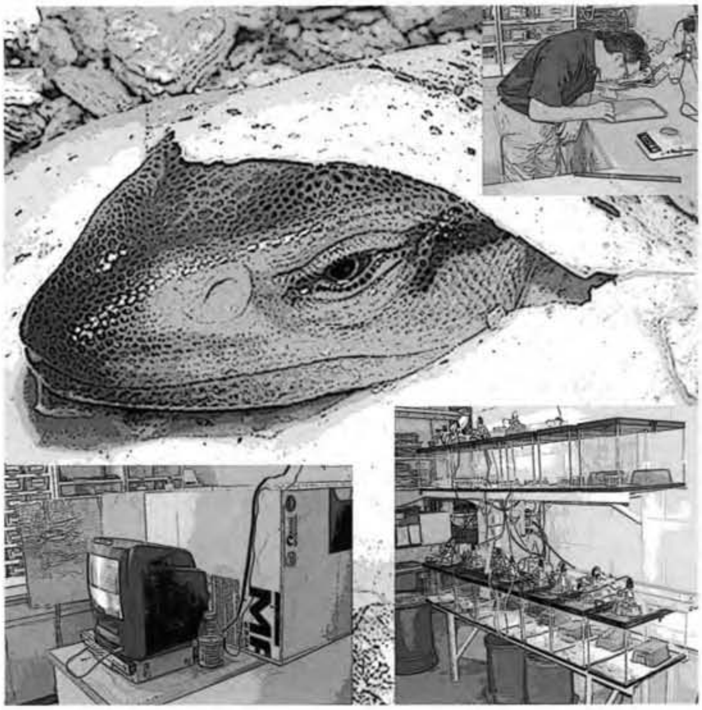
Herpetological Review, 2005, 36(2), 103–106.

Herpetological Research in Zoos: A Contemporary Assessment

CLAY M. GARRETT
Department of Herpetology - Fort Worth Zoo
1989 Colonial Parkway - Fort Worth, Texas 76110, USA
e-mail: cgarrett@fortworthzoo.org

Over the last 15 years numerous authors have addressed the value of zoo-academic collaborations (Card et al. 1998; Chiszar et al. 1993a; 1993b; Cooper et al. 1996; Garrett and Chiszar 1996; Kreger 1993; Murphy and Chiszar 1989; Pough 1993). Consequently, many peer-reviewed papers have been published as a result of successful partnerships between zoo and academic colleagues. Although there are numerous zoo and academic herpetologists who work jointly on conservation projects, this paper addresses collaborative projects of a basic scientific nature.

Card et al. (1998) conducted a survey revealing 164 technical papers published during 1987–1997 contributed by zoo herpetologists, and determined that members from three institutions contributed 80% of those papers. In the eight years since the aforementioned review there has been a considerable decline in the number of manuscripts resulting from zoo-academic collaborations. Noteworthy exceptions include the following: Ferguson et al. (2003) investigated whether Panther Chameleons (*Furcifer pardalis*) bask to regulate endogenous vitamin D3 production; Hartdegen and Chiszar (2001) looked at prey chemical discrimination in Gila Monsters (*Heloderma suspectum*); Cooper and Hartdegen (1999) examined chemoresponse to plant and animal cues in *Scincella lateralis*; Cooper and Hartdegen (2000) explored lingual and biting responses to prey chemicals by ingestively naïve *S. lateralis*; Murphy et al. (2002) compiled various studies on Komodo Dragons (*Varanus komodoensis*) resulting in a book published by Smithsonian Institution Press; Aucone et al. (2003) conducted studies with Chuckwallas (*Sauromalus obesus*) to determine the levels of 25-hydroxyvitamin D following exposure to Westron® self-ballasted mercury vapor lamps; Ferguson et al. (2004) published a book on the natural history, conservation, and captive management of Panther Chameleons (*Furcifer pardalis*); and Ewert et al. (2004) documented temperature dependent sex determination and ontogeny in Pancake Tortoises (*Malacochersus tornieri*). Clearly, there are a handful of prolific collaborators, but overall there is a lack of breadth regarding experimental research among zoo herpetologists. Herein I identify some of the problems, and suggest how the occurrence of collaborations with academic colleagues might increase.



Savanna Monitors (*Varanus albigularis*): test subjects for collaborative experiments at Fort Worth and Dallas Zoos.

Some of the reasons for the paucity of collaborations include: lack of knowledge and/or inspiration on the part of zoo staff; perceived unimportance by management, both at the curatorial level and above; dwindling number of academic herpetologists who place emphasis on research in zoos due to de-emphasis of natural history and related fields in universities (as noted by Chiszar and Smith, 2005); and no convenient medium for broad-scale communication about ideas for interesting projects.

Most zoo herpetologists are really good at what they typically do, which is to care for and exhibit diverse living collections of amphibians and reptiles. It is also true that they tend to have a global knowledge of herpetofauna, and are generally well read. But the literature they consume is often descriptive in nature, thus formal papers pertaining to herpetological science are frequently unseen. This is an important detail, for without a basic knowledge of contemporary herpetological science, one would essentially speak a different language from those in mainstream academia. And unless we speak the same language there can be no meaningful relationships with those in academia. The best way to remedy this problem is for curators to encourage, if not require, their staff to stay abreast of current herpetological news. Further, the acqui-

sition of knowledge is intrinsically tied to the act of being inquisitive, so curators should always push their staff to explore the systematics, ecology, and physiology of amphibians and reptiles, and ensure that they have easy access to relevant scientific literature.

Likewise, academic herpetologists are really good at what they typically do. Often times, however, they have scant knowledge of the many resources zoos have to offer, and their ties with zoo herpetologists are weak or non-existent. The logical fix for this problem is to enhance communication between zoo and academic herpetologists and make the resources available at zoos more readily apparent and accessible to those in academia. See below for more on this topic.

Allow me to share a telling anecdotal experience. I was employed in the department of herpetology at the Dallas Zoo from 1985–1995. A ritual at the time was a morning meeting, lasting about an hour (a tradition that continues at Dallas today) that centered around the break table. These gatherings were an opportunity to discuss the day's agenda (medical procedures, new exhibits, research projects, animal transactions, etc.), and to talk about herpetology in general. There are several important points here: 1) everyone was equal at the break table so the curator could not or did not impose his ideas because of his position. If he pushed a particular idea for acceptance, it only was added to our program because his argument was sound; 2) there were ground rules—be courteous to one another and not try to intimidate with posturing, etc. Since we worked closely with each other, it was important to encourage a collegial interaction with a bunch of alpha types who, as a rule, were somewhat selfish; 3) there were limited resources so we had to make sure that what we did made sense and was a mutually acceptable course of action by the majority; 4) all of us needed to be able to defend our ideas and engage in a Socratic dialectic with the top professionals in our field.

Frequently we shared the company of prominent academic herpetologists (Walter Auffenberg, Roger Avery, Bayard Brattstrom, Bill Branch, Angus d'Bellairs, Daniel Bennett, Edmund Brodie, Jr., Jonathan Campbell, Charles Carpenter, Dave Chiszar, Joseph Collins, Roger Conant, William Cooper, Jr., David Crews, Ben Dial, James Dixon, Gary Ferguson, Neil Ford, Darrel Frost, Carl Gans, Bill Gehrmann, James Gillingham, Howard Gloyd, Harry Greene, David Hardy, Victor Hutchison, Frances Irish, Elliott Jacobson, Konrad Klemmer, Bill Lamar, Chris McAllister, Sherman and Madge Minton, M. Graham Netting, Eric Pianka, George Pisani, William Pyburn, Gerald Raun, Gordon Schuett, Edward Taylor, Donald Tinkle, Stanley Trauth, Paul Weldon, Martin Whiting, Wayne and Tom Van Devender, and others) who were passing through—stopping by to admire our collection and to harass curator James Murphy about all manner of things, not the least of which was his sartorial ineptitude. Humor aside, those of us in the department during those times had the good fortune of learning in this informal classroom with non-zoo colleagues who brought a suite of interesting ideas independent of zoo matters for us to consider. This was a place where all of us could test our wings with our peers, leading later to fruitful interactions. To his credit, James Murphy fostered this intellectual environment often at the frustration of the zoo director and fellow curators…as in…why are you guys still sitting around the break table drinking coffee…don't you have work to do? Of course, we always had plenty to do. We were encouraged to structure our days efficiently so that if an unexpected guest stopped by, there was time to visit. Accordingly, we generated project lists with agreed upon deadlines, and strived to complete routine duties as quickly as possible. Good time management also permitted us to work on other projects unrelated to collection maintenance. The benefits to this organizational strategy were that it built self-determination and good work habits, and negated the need for supervisors to micromanage staff—clearly a plus for both employee and employer!

It seems that the most important manifestation of these gatherings was the inspiration to think on a higher plane—to encourage inquisitiveness and develop independent lines of inquiry. And the effect of those morning meetings has been lasting, as evidenced by the number of us who have gone on to collaborate with many of the persons mentioned previously. When I think of factors that have led to successful partnerships, a scenario similar to that just described seems paramount. Further, I must emphasize how important those times were in influencing my overall philosophy of management and program building. Since the mid-1990s, several of us have moved into management positions in herp departments at other zoos, and we are working to establish a similar environment at our institutions.

The fact that experimental research is not on the "front burner" in more zoo herp programs is baffling. Murphy (2005) points out that zoo herpetologists devote considerable time to American Zoo & Aquarium Association (AZA) related activities, such as preparing studbooks and Taxon Management Accounts (TMAs), administering Taxon Advisory Groups (TAGs), etc., believing these activities are research, which they are not. This is not to say that these endeavors are unimportant, for they are. They should not, however, be confused with empirical research. Given the broad range of behaviors associated with amphibians and reptiles, there are myriad projects that can be implemented utilizing a diverse herpetological collection. Projects that explore basic organismal topics such as reproduction, behavior, and comparative physiology are important. Some specific reptilian psychobiological processes that are candidates for assessment include: activity cycles, cover-seeking behavior, anti-predator tactics, stress, foraging behavior, etc. (for more examples see Chiszar et al. 1993a; 1993b). Apart from experiments that have obvious applied value (see Ferguson et al. 1996; Burghardt et al. 1996), there are many opportunities to answer questions having theoretical relevance (see Kardong 1996; Garrett et al. 1996; Cooper et al. 1996). As Chiszar et al. (1993b) suggest "qualitative analysis of the presence or absence of suspected adaptive phenomena although useful in their own right, can easily give rise to theoretical insight and advanced understanding of phenomena that are incompletely known at present." Utilizing zoo herp collections to this end should be an integral component of progressive zoo herpetology. And the interest is there. In May of 2004, SSAR Zoo Liaison Committee member Brian Aucone (Curator of Herpetology – Oklahoma City Zoo) queried herpetologists at 46 US and European zoos as to whether they would be interested in collaborating with academic herpetologists for scientific research—100% indicated they would.

Non-invasive experimental research should be an easy sell to upper administration in zoos, as long as the primary facets of traditional operations (animal health, public display, education) are met. In-house research typically has negligible budget impact and can result in important contributions. And the experimental pro-

cess is, in and of itself, enriching. Apart from potentially answering interesting questions, the process often generates new questions, taking the investigators in completely new directions. Another fortuitous advantage of collaborative research is that it draws positive attention to the zoo—ever important in a time when zoos must constantly justify why they keep animals. Common sense would dictate that it is our responsibility to maximally utilize our collection.

There is little to be done about the falling number of herpetologists focusing on ecology in academia (which directly effects zoo collaborations), save for the constant bleating about its importance. What we can do is make it easier for the academic and zoo herpetologists to communicate. An historical problem has been the absence of a convenient medium for dialogue and the exchange of ideas. Accordingly, one of the goals for the SSAR Relationships with Herpetologists at Zoological Parks Committee for 2005 is to establish a web-based forum (as part of the SSAR website) to facilitate communication. As committee chair, I have volunteered to take on this task, both as developer and moderator. The forum will be accessible from the SSAR Homepage (Zoo Liaison button), and will be seamless, meaning it will link directly and have the same user interface as the main site. Herpetologists will also have the luxury of viewing threads and posts of all who participate, therefore augmenting dissemination of ideas. With this new tool at our disposal, communication should be considerably more efficient.

An artifact of communication through the web forum may be the increased desire of zoo herpetologists to attend professional meetings. While quite a few zoo peers do attend IHS, SWAN, SSAR/ASIH/HL meetings, it would certainly be conducive to collaborative relationships for more zoo herpetologists to attend academic symposia. These meetings, especially the larger ones, always engender excitement, and are the perfect venue for networking and exchange of ideas. Zoos are more likely to financially support registration fees and travel to AZA-sponsored events, so there exists the challenge of persuading zoo administrators to allocate a portion of their budget for academic herp meetings. Curators should certainly consider such meetings an important part of professional development for herp staff.

One of the most difficult aspects of implementing a research program in a zoo setting is getting projects off of the ground. While there will always be challenges with staff, administration, etc., the bottom-line is that curators just have to make it happen . . . no need to wait for planets to align. Collaboration with other individuals makes this considerably easier, as long as projects do not suffer scope creep (a corporate term for projects where focus is lost and deadlines are missed because too many people are allowed to have input and/or make decisions). A number of us at various zoos (all of whom were in the Dallas Zoo's herp department at some point) are working on what we hope will be a model program. We have formed a "consortium" of sorts where we view our inventories as a collective, thereby allowing us access to a greater diversity of species and increased sample sizes. We have identified numerous projects (some of which involve moving eggs and neonates between zoos), assigned principle investigators, and are presently carrying out experiments.

Every collaborative relationship is different. What works well for some, may not work well for others, thus investigators will tackle the issues of project planning and initiation in different ways. Chiszar and Smith (2005) offer some insightful comments on their experiences collaborating with zoo herpetologists, and they outline program attributes that have contributed to meaningful collaborations. Embracing those protocols can certainly facilitate new relationships. I should add that while Dave Chiszar and Hobart Smith humbly insist that their efforts have not been special in any way, I know first-hand that they have—namely their sharing of knowledge and willingness to encourage and support eager zoo herpetologists.

Pough (1993) suggests that involving students in zoo research projects is an excellent way to tap the resources of academic institutions, and notes that most colleges and universities offer academic credit for research projects supervised by a faculty member. In fact, many of these supervised projects result in peer-reviewed publications. Currently, numerous zoo herp departments offer intern programs where both undergraduate and graduate students work summer semesters for biology and/or research credit. Our experience at the Fort Worth Zoo has been that interns provide a great service while learning about animal behavior, husbandry, record keeping, etc. Many of these student employees will doubtless hold academic positions in the future, thereby paving the way for fruitful interactions. Zoo herpetologists should also become more involved in academic lab and field projects as research assistants, as academics with sizable grants may be interested in hiring temporary help from the non-student pool.

One more thing . . . it is rare for academic herpetologists to "drop the ball" when it comes to completion of collaborative projects. While I do not mean to suggest that indolence prevails among zoo herpetologists, we should make every effort to finish projects that are started. Nothing sours professional cooperation quicker than partners who do not follow through. Time is important for all of us, and mutual respect in this regard will serve everyone well.

Did *Desmognathus* Salamanders Reinvent the Larval Stage?

RICHARD C. BRUCE*

e-mail: ebruce1563@aol.com

Until recently the plethodontid subfamily Desmognathinae, with 20 species, has been considered a monophyletic lineage of morphologically specialized salamanders, standing as the sister taxon of the 350-plus species of the subfamily Plethodontinae, the latter comprising the tribes Hemidactyliini, Plethodontini, and Bolitoglossini (Larson et al. 2003; Schwenk and Wake 1993; Wake 1966). The biphasic life cycle, featuring a free-living larval stage, has been hypothesized as the ancestral life-history mode of desmognathines; the three species having direct development have been viewed as specialized, derived forms (Hairston 1987; Wake 1966).

Recent studies of molecular systematics of desmognathines have shown that the direct-developing species, the large, elongate *Phaeognathus hubrichti* and the miniaturized *Desmognathus wrighti* and *D. aeneus*, occupy more basal positions in the taxon, leading to the hypothesis that direct development was ancestral in desmognathines (Rissler and Taylor 2003; Titus and Larson 1996).

Three newer studies have re-evaluated the relationships of plethodontids generally, and have supported Titus and Larson's (1996) and Rissler and Taylor's (2003) interpretation of desmognathine evolution. In an investigation of plethodontid mitochondrial genomes, Mueller et al. (2004) showed that desmognathines nest within a mix of direct-developing forms, including *Plethodon*, *Hydromantes*, and *Aneides*, and fall out as the sister taxon of *Ensatina* (Fig. 1). These authors (Mueller et al. 2004: Fig. 3) posited three equally parsimonious evolutionary scenarios to account for life-history diversification within the framework of their phylogeny. Although they left this as an unresolved problem, each of the three scenarios requires, for desmognathines, the evolution of biphasic life cycles in descendants from direct-developing ancestors, and thus the re-evolution of a free-living larval morph within this lineage. Second, Chippindale et al. (2004), using both morphological and molecular characters, found that desmognathines fall within the traditional plethodonine (tribal) clade, and stand as the sister taxon of *Aneides–Ensatina* (Fig. 2). They speculated that desmognathines re-evolved a biphasic life cycle under competitive pressures from other terrestrial plethodonines in species-rich Appalachian Mountain ecosystems. Finally, Macey (2005), in a reanalysis of the Mueller et al. (2004) mitochondrial genomic dataset, reported that desmognathines fall within a plethodonine–*Hydromantes* lineage, and recovered *Desmognathus–Phaeognathus* as the sister lineage of *Aneides–Ensatina–Hydromantes* (Fig. 3). This paper did not directly address life-history evolution. Chippindale et al. (2004) proposed a new taxonomy for plethodontids in which the traditional subfamily Desmognathinae is abolished, with the genera *Desmognathus* and *Phaeognathus* recognized as the supergenus *Desmognathus*. In the remainder of the present paper I use the term desmognathan for the monophyletic clade of *Phaeognathus* and *Desmognathus*, and will refer to plethodontid subfamilies by the new names suggested by Chippindale et al. (2004) and followed by Macey (2005) (see Figs. 2, 3).

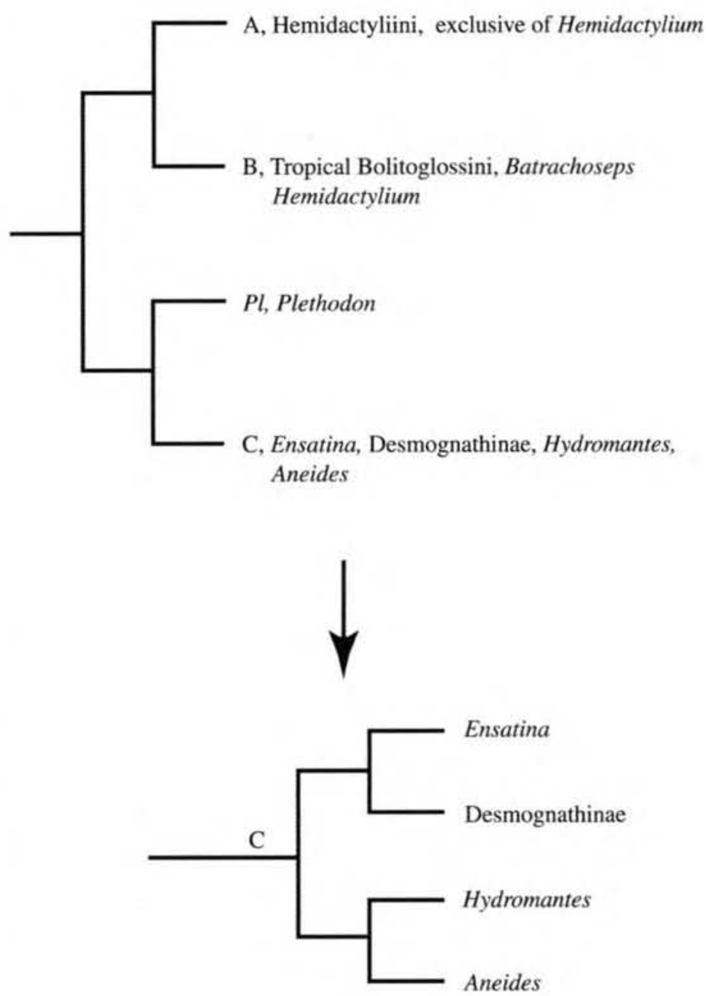

FIG. 1. Main features of the mitochondrial genomic phylogeny of Mueller et al. (2004: Fig. 2).

The Mueller et al. (2004), Chippindale et al. (2004), and Macey (2005) analyses raise numerous questions concerning the evolutionary history and relationships of desmognathans. I address the following: (1) What is the sister taxon of plethodontids, and how does resolution of this question inform understanding of life-history evolution in plethodontids generally and desmognathans specifically? (2) What is the likelihood that desmognathan morphology is a product of convergent evolution (homoplasy) for the three morphological character sets that Mueller et al. (2004) evaluated? (3) What other morphological characters contribute to the resolution of desmognathan relationships? (4) What is the status of the three direct-developing members of the clade in reference to their morphology, developmental biology, life history, and ecology? (5)

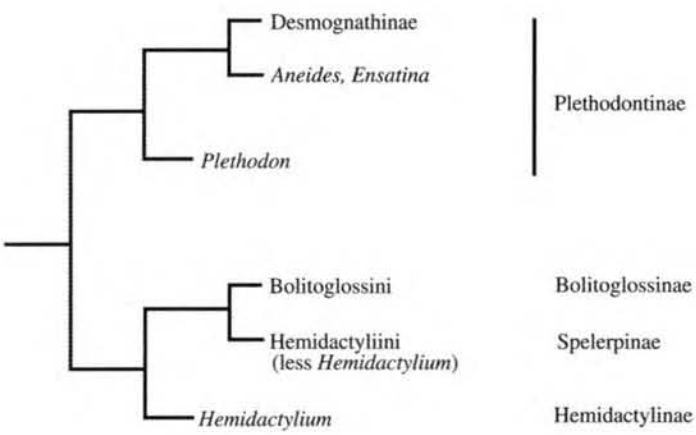

FIG. 2. Phylogeny of Chippindale et al. (2004: Fig. 4) based on combined data (molecular + morphology). Names in the right-hand column are the subfamily assignments proposed by the authors.

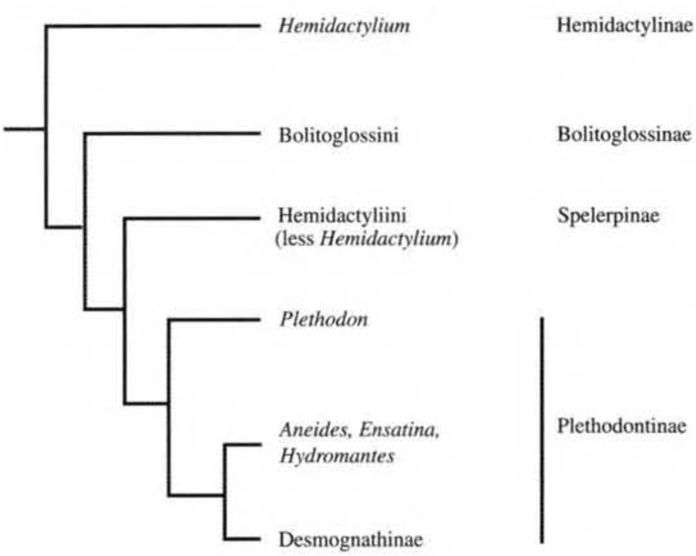

FIG. 3. Macey's (2005: Fig. 1A) most parsimonious tree based on the mt-DNA dataset. Subfamilies follow Chippindale et al. (2004).

How realistic is the ecological scenario posited by Chippindale et al. (2004) for the re-evolution of biphasic life cycles in desmognathans? (6) What weight should be assigned, in plethodontids, to an evolutionary transition from a biphasic life cycle to direct development, as opposed to the reverse?

In addressing these questions, my arguments are based on (1) application of outgroup comparison in phylogenetic inference, i.e., that the ancestral character state is most likely the one that is most widely distributed among taxa outside the group in question, and (2) Dollo's law of irreversibility, i.e., that complex characters, once lost in evolution, are unlikely to be regained (Dollo 1905; Gould 1970).

1. The sister family question

Whereas Larson and Dimmick (1993) assigned Amphiumidae as the sister family of Plethodontidae, Larson et al. (2003) noted the uncertainty of relationships among Amphiumidae, Plethodontidae, and Rhyacotritonidae. Chippindale et al. (2004) recovered Amphiumidae as the sister family of Plethodontidae, with Rhyacotritonidae as the sister lineage of this clade. The analyses of Mueller et al. (2004) and Macey (2005), both of which omitted Amphiumidae, supported a sister-group relationship between Rhyacotritonidae and Plethodontidae. Both Amphiumidae and Rhyacotritonidae are small families, each with a single genus, with three and four species, respectively. The species of *Amphiuma* are highly aquatic, specialized, partially paedomorphic salamanders; yet the gilled larval period is apparently brief and larvae may not feed in the larval stage (Gunzburger 2003; Ultsch and Arceneaux 1988). Thus—uniquely—life-history modes in *Amphiuma* approach direct development, even though metamorphosis is incomplete and adults retain some larval features. Rhyacotritonids resemble plethodontids in the reduction of lungs and absence of an ypsiloid cartilage (Good and Wake 1992), some aspects of cloacal anatomy (Sever et al. 2004a,b), and courtship behavior, which features a tail-straddling walk identical to that of plethodontids (Rudenko et al. 2003). The species of *Rhyacotriton* are mountain-stream salamanders; the biphasic life cycle involves a multi-year larval period (Nussbaum and Tait 1977), similar to that of many biphasic plethodontids (Bruce 2003). Thus, a sister-group relationship between rhyacotritonids and plethodontids infers a stream-dwelling common ancestor with a biphasic life cycle.

In their phylogenetic construct of developmental modes, Chippindale et al. (2004: Fig. 4) coded amphiumids as biphasic. They did cite evidence (Gunzberger 2003) that amphiumids could be considered direct developers. In any case, the early life histories of *Amphiuma means* (Gunzburger 2003) and *A. tridactylum* (Ultsch and Arceneaux 1988) are similar to those of *Phaeognathus hubrichti* (Means 2003) and *Desmognathus aeneus* (Harrison 1967; Valentine 1963), which Chippindale et al. (2004) considered direct developers. However, coding amphiumids as direct developers would require postulating a direct development–biphasic transition in the hemidactyline and spelerpine lineages, as well as in (most) desmognathans. This might be a difficult argument to sustain. Adding rhyacotritonids to the mix reinforces assignment of the ancestral life-history mode as biphasic.

2. Morphological homoplasy

Mueller et al. (2004) evaluated the following three morphological characters in reference to their mitochondrial genomic phylogeny: (1) hind-limb toe number, (2) tongue structure, and (3) tail autotomy. Toe number is uninformative for desmognathans; the ancestral number is five, and this state is retained in all members of their major *Pl*–C clade to which desmognathans belong. Reduction from five to four toes has occurred in several lineages within their major AB clade.

Three tongue types are found in plethodontids: protrusible, free, and attached projectile. The protrusible tongue is the simplest, and is least modified from the ancestral condition based on outgroup comparisons. It is retained in desmognathans and in the genera *Plethodon* and *Aneides*. However, in other members of the *Pl*–C clade, *Ensatina* (the putative sister group of desmognathans) has an attached projectile tongue, whereas *Hydromantes* has a free tongue.

The third character considered by Mueller et al. (2004) is tail

autotomy, with three states. The simplest is a thick-based tail with no specializations for autotomy and rapid wound healing. This condition is found in desmognathans and most spelerpines, as well as in close outgroups, and thus can be considered the ancestral state. The more specialized states are slender- and constricted-based tails, with various provisions for breakage and wound healing. Mueller et al. (2004) proposed that tail autotomy evolved in ancestral plethodontids, and that evolution of a thick-based tail occurred independently in aquatic and semi-aquatic spelerpines and desmognathans as an adaptation for aquatic locomotion. Based on outgroup analysis, such a scenario would represent a reversal. *Ensatina*, the putative sister taxon of desmognathans, has a constricted-based tail.

Based only on information provided by Mueller et al. (2004) on these three sets of morphological characters, it seems remarkable that desmognathans have retained character states for all three that can be inferred as ancestral vis-à-vis close outgroups, yet in the mitochondrial genomic phylogeny they nest deeply in a clade comprising members exhibiting derived morphological states. The sister-group relationship of *Ensatina* and desmognathans appears especially suspect, inasmuch as desmognathans otherwise share few traits with *Ensatina*, either in morphology, ecology, or life history.

3. Other morphological characters

The principal morphological characters that define desmognathans are nine skeleto-muscular features of the head, trunk, and limbs (Schwenk and Wake 1993). The latter authors interpreted these as conjoint adaptations for feeding and for burrowing by head wedging in streams. They argued that the traits reflect a secondary entry into streams by adult desmognathans. But, given that the traits are shared across the supergenus, such an evolutionary scenario would seemingly necessitate some degree of aquatic ancestry for the direct-developing species as well as for the biphasic members of the clade.

In comparing skull development in the biphasic *Desmognathus quadramaculatus* and direct-developing *D. aeneus*, Marks (2000), in assuming that the biphasic life cycle is the ancestral state in desmognathans, addressed the question of evolution of direct development by (1) recapitulation of the ancestral ontogeny, which is accelerated so that metamorphosis occurs before hatching, versus (2) ontogenetic repatterning, wherein the ancestral pattern is modified. One key element in her comparison was the palatopterygoid bone, absent in *D. aeneus* but present in *D. quadramaculatus* as well as in larvae of *Eurycea bislineata*. Parsimoniously, this requires that the evolution of direct development in desmognathans, as expressed in *D. aeneus*, involved ontogenetic repatterning. Conversely, if direct development represents the ancestral state in desmognathans, the palatopterygoid would have had to have been reinvented in biphasic desmognathans (if in fact it is also absent in *Phaeognathus* and *D. wrighti*). According to Marks (2000: p. 273), "... evolution of direct development via repatterning involves an alteration of the ancestral ontogeny. Thus, it may be difficult for larval forms to re-evolve from direct-developing ancestors." And later (Marks 2000: p. 275), "... evolution of direct development via ontogenetic repatterning may preclude subsequent re-evolution of species with larval development." Marks's (2000) argument is convincing insofar as the evidence allows, but what are needed to resolve the question are embryological data for the other two species (*D. wrighti* and *P. hubrichti*) of direct-developing desmognathans.

An additional set of characters bearing on desmognathan relationships is the hyobranchial skeleton, especially variation in morphogenesis of the epibranchial cartilages in embryos and larvae (Alberch 1987). Three epibranchial cartilages develop embryologically in most hemidactyline and spelerpine plethodontids, although two or three species, *Hemidactylium scutatum* and *Eurycea longicauda/guttolineata*, have either three or four epibranchials (Rose 1995a). Embryos of *Plethodon cinereus* develop three epibranchials (Dent 1942). In contrast, desmognathans, including *D. aeneus* and *D. quadramaculatus*, have four epibranchials (Marks 2000). Given that other families, Proteidae excepted, also develop four epibranchials, the desmognathan condition is most parsimoniously interpreted as ancestral for plethodontids.

In plethodontids, bolitoglossines excepted, the embryonic and larval first epibranchial undergoes replacement (versus remodeling) at metamorphosis by the single adult epibranchial that develops in its position (Alberch 1987; Alberch and Gale 1986; Rose 1995b). Alberch (1987) proposed that this feature, unique to plethodontids, was an adaptation of biphasic ancestral plethodontids that facilitated metamorphosis and allowed independent evolution of larval and adult morphology.

One feature of the sensory system of phylogenetic significance is the lateral line. Lateral line organs are found in larvae and aquatic adults in all urodelan families; thus the presence of the lateral line is postulated as the ancestral state. In plethodontids lateral line organs are found in spelerpines and in larvae and adults of aquatic and semiaquatic species of desmognathans; they are absent in direct-developing *D. aeneus* and *D. wrighti* and in direct-developing members of other lineages (Collazo and Marks 1994; Dent 1942). If desmognathans stem from a direct-developing ancestry, they have necessarily re-evolved the lateral line system.

4. Direct-developing desmognathans

The evolution of small body size in desmognathan salamanders is correlated with accelerated development to metamorphosis and sexual maturation (Beachy and Bruce 2003). *Desmognathus aeneus* and *D. wrighti* are among the world's smallest salamanders, similar to many species of *Thorius* (Bruce 2000: Table 4) in mean and maximum adult sizes (Harrison 1967; Hining and Bruce 2005; Organ 1961a,b). Given that no other members of the *Pl*–C clade of Mueller et al. (2004) exhibit such small sizes, miniaturization in these species is undoubtedly a derived trait. Miniaturization is correlated with a high rate of development to sexual maturation (Harrison 1967; Hining and Bruce 2005), inasmuch as age at maturation is lower in both species than in other, larger *Desmognathus* (Bruce et al. 2002; Castanet et al. 1996). Thus, I suggest that direct development in both *D. aeneus* and *D. wrighti* is an evolutionary consequence of heterochronic acceleration in developmental rate that eliminated the free-living larval stage, lowered age at sexual maturation, decreased generation time, and promoted small body size; i.e., a "matrix of acceleration" (Ryan and Bruce 2000). Possible ecological factors eliciting selection for these traits include competition and predation acting in diverse species assemblages along the rich resource gradient of southern Appalachian ecosystems (Bruce 1996; Hairston 1986, 1987).

The biology of the third direct-developing desmognathan, *Phaeognathus hubrichti*, is poorly known. It is a secretive burrower, highly derived in morphology (e.g., 21–23 trunk vertebrae vs. 15 in other desmognathans). Basic life-history data are sketchy. Whereas hatchlings emerge at a large size with well-developed gills, the larvae do not feed, and they metamorphose within a few days (Means 2003). Age at sexual maturation is estimated as 5–6 years in females and probably earlier in males, based on skeletochronological data of 11 individuals (Parham et al. 1996). Although these findings suggest acceleration in growth and developmental rates in comparison with the larger species of *Desmognathus* (Bruce et al. 2002; Castanet et al. 1996), verification awaits further data on growth and maturation in *Phaeognathus*.

5. The Ecological Scenario

Chippindale et al. (2004) proposed that selection favoring re-evolution of a biphasic life cycle in *Desmognathus* derived from competition with terrestrial plethodontines (e.g., *Plethodon*) in species-rich salamander assemblages of the Appalachian Mountains. They overlooked the likelihood that such assemblages contained semiaquatic and aquatic spelerpines of the genera *Eurycea*, *Gyrinophilus*, and *Pseudotriton*. Clade ages in the latter taxon are in fact greater than those of desmognathans (Larson et al. 2003). From an ecological perspective, the evolution of biphasic life cycles in amphibians is related to the causes and consequences of ontogenetic niche shifts in relation to differences in resources, competition, and predation in the aquatic and terrestrial habitats (Roff 2002; Rowe and Ludwig 1991). Extant species of biphasic desmognathans and spelerpines overlap considerably in body size, diet, and life history (Petranka 1998). Interactions among them are incompletely understood. Nevertheless, the ecological–evolutionary model of Chippindale et al. (2004) would seemingly have taken desmognathans "out of the frying pan into the fire" in the competitive milieu of Appalachian salamander assemblages.

Conversely, in assuming a biphasic ancestry of desmognathans, the same objection might be raised for the evolution of the direct-developing, terrestrial members of the lineage. However, *Desmognathus aeneus* and *D. wrighti* are miniaturized forms, smaller than any extant members of *Plethodon*, and they thereby occupy unique adaptive zones within the Appalachian plethodontid assemblage. Their evolutionary trajectories may have involved entry into unoccupied, resource-rich terrestrial niches, which served to reduce predation and competition from their more aquatic congeners (Bruce 1996; Hairston 1986, 1987). Similarly, as noted above, *Phaeognathus hubrichti* appears to occupy a unique niche, unlike that of other North American salamanders.

6. Evolutionary reversals

The acquisition in a descendant of a biphasic life cycle, with a free-living larval stage, from a direct-developing ancestor, which itself had evolved direct development from an earlier biphasic ancestor, might constitute an exception to Dollo's principle; i.e., an organism or a complex organ system never returns exactly to its former state (Dollo 1905). This postulate can be restated within the framework of probability theory: Reversal of a complex adaptation to its ancestral state involves so many independent steps that the laws of probability make re-evolution of the ancestral condition highly unlikely (Gould 1970). In the present case this generates the question whether the larval morph of plethodontid salamanders is sufficiently complex to make the probability of its re-evolution effectively nil. Resolution of the question requires evaluation of morphogenesis in the biphasic and direct-developing lineages within the framework of the phylogenetic hypotheses generated by the newer molecular techniques.

In plethodontid salamanders, the derivation of a descendant with a biphasic life cycle from a terrestrial ancestor with direct development would involve the re-evolution of a free-living larva adapted to respire with external gills and feed by suction feeding, and having an aquatic locomotor system, lateral line sensory organs, plus other morphological features associated with aquatic life. Moreover, such a scenario requires the re-evolution of a complex metamorphosis involving many organ systems, as well as the underlying physiological/endocrinological system that regulates the transformation. It is unlikely that an evolutionary change of this level of complexity (as expressed in the biphasic desmognathans) could be accomplished by simple heterochronic retardation of embryonic development starting with a direct-developing ancestor, given that in embryos of direct-developing plethodontids, including desmognathans, the requisites for a free-living existence in aquatic environments have been lost or have been obscured by ontogenetic repatterning (Collazo and Marks 1994; Marks and Collazo 1998; Wake and Hanken 1996).

In contrast, the evolution of direct development from a biphasic ancestry represents simplification of the ancestral life cycle that can be achieved through accelerated development, involving loss of ancestral larval characters and simplification of metamorphosis and its physiological controls. Thus, my response to the assertion of Mueller et al. (2004) that "Discrimination among these scenarios [of life history evolution] will require weighting either the loss or reevolution of larvae ..." is that the probability of evolving direct development from a biphasic ancestry far outweighs that of the reverse.

Chippindale et al. (2004) calculated probabilities that ancestral desmognathans were direct developing, over a range of hypothetical relative transition rates between alternative life-history modes. Their calculations generate probabilities below 50% only by assuming that the probability of the direct development to biphasic transition is several orders of magnitude lower than the reverse. However, this may not be an unreasonable assumption, given the morphogenetic constraints involved in re-evolving a larval stage.

Conclusions.—Contrary to the molecular evidence, data from morphology, embryology, and life history, in comparison with other urodelan families, all suggest that a biphasic life cycle is ancestral in plethodontids generally and in desmognathans specifically. In desmognathans the retention of ancestral states for an array of unrelated characters is difficult to account for on the basis of homoplasy. Moreover, the three direct-developing species of the subfamily are all specialized in body size and other characters, and they occupy unique adaptive zones. Direct development would appear to represent an evolutionary correlate of these derived traits.

The principal inconsistency in the Mueller et al. (2004) phylogeny is the putative sister-group relationship of desmognathans and *Ensatina*. This inconsistency is removed in Macey's (2005) re-evaluation of the mitochondrial genomic dataset, wherein the position of *Ensatina* shifts to a clade including *Aneides–Ensatina–Hydromantes*, forming the sister group of *Phaeognathus–*

Desmognathus. The Macey phylogeny requires no transitions from direct development to a biphasic life cycle. Although Chippindale et al. (2004) argued for a reversal from direct development to larval development in desmognathans, in their phylogeny retention of a biphasic life cycle in ancestral desmognathans, hemidactylines, and spelerpines would require the evolution of direct development in *Plethodon*, *Aneides* + *Ensatina*, and Bolitoglossini, as well as in three desmognathan lineages, but no reversals. Given the multiple derivations of direct development in anurans, caecilians, and tetrapods generally, this would appear to be a more likely scenario than the reinvention of biphasic life cycles by plethodontid salamanders.

From my perspective, the most compelling questions stemming from these surprising new phylogenies concern the ecological aspects of life-history evolution. I still maintain that streamside species with the brief larval periods and small metamorphic sizes represent valid models of the "ancestral" desmognathan (Bruce 1991). Nevertheless, it would be valuable to have more comprehensive, comparative data on embryogenesis and early life history in a variety of desmognathans, including *Phaeognathus hubrichti* and *Desmognathus wrighti*, and in their putative plethodontine relatives. Experimental studies on plasticity in ontogenetic niche shifts and its ecological and genetic basis in desmognathans should shed light on the evolutionary potential for transitions between life-history modes in this clade. Also needed are broader scale experimental studies than have heretofore been conducted on ecological interactions among spelerpines and desmognathans, in the aquatic phases especially, in species-rich communities in the Appalachians and elsewhere.

Acknowledgments.—I thank C. K. Beachy, D. A. Beamer, and T. J. Ryan for helpful discussions of these issues. P. T. Chippindale and D. B. Wake provided insightful reviews of an earlier version of the manuscript.

Why Should Reaquisition of Larval Stages by Desmognathine Salamanders Surprise Us?

RONALD M. BONETT

It is understandable that Bruce (2005) questions interpretation of our independent studies concerning plethodontid life-history evolution. Larval development is found in all ten families of salamanders, and only members of Plethodontidae exhibit direct development from deposited eggs (Salthe 1969). Nevertheless, all analyses of mitochondrial DNA (Macey 2005; Mueller et al. 2004; Titus and Larson 1994), nuclear DNA (Chippindale et al. 2004), and even of the combined morphological and molecular data (Chippindale et al. 2004), indicate that desmognathine salamanders with larval development are deeply nested within direct-developing clades. Given the new and robust phylogenetic hypotheses, the most parsimonious interpretation of these results is that the free-living larval phase has re-evolved. We think that explorations such as those presented by Bruce (2005) are important contributions toward explaining these findings. However, invocation of generalizations such as Dollo's "Law" (which states that complex states cannot re-evolve once lost; Hall 1998) is not the most appropriate approach to the analysis of real data sets. Empirical analyses of Dollo's Law show that genes controlling developmental processes can indeed remain dormant for long time periods, up to 10 million years, and then be reactivated to express traits previously "lost" within clades (e.g., Marshall et al. 1994). Within salamanders there have been demonstrable reversals of other life-history traits, notably a return of metamorphosis in taxa deeply nested within otherwise permanently larval forms (Bruce 1976; Chippindale et al. 2000; Shaffer 1984; Sweet 1982). Also, there is surprising plasticity in life-history traits associated with metamorphosis and even egg retention and oviductal development (Lanza and Piero 2001; Wake 1989; Wake and Hanken 1996).

Perhaps, as Bruce (2005) argues, life history evolution has been highly non-parsimonious (i.e., direct development has independently evolved many times within Plethodontidae), and what has been called "direct development" is, instead, a heterogeneous set of non-homologous states. Labeling his argument as a "point of view" is appropriate. We think that his arguments contain elements of speculation, whereas ours are based on direct interpretations of the phylogenetic data. Refuting the possibility of a reversal from direct development to a free-living aquatic larval stage in desmognathines would require the acceptance of at least four or five independent origins of direct development. This would also imply that "direct development" is not one but many states (e.g., Wake and Hanken 1996); if so, there has been far more diversity of life-history modes in plethodontids than has been recognized previously. Our new phylogenetic hypotheses are based largely

on new molecular datasets; because they are hypotheses, we are actively engaged in gathering additional data to test them. We need to develop other datasets and integrate our studies in such a manner as to effectively test and reject alternative hypotheses of plethodontid relationships until such hypotheses can generally be viewed as robust, even if they conflict with more classical hypotheses for the evolution of morphology and life-history evolution in this group. The newly discovered Asian plethodontid salamander, *Karsenia koreana*, also appears to be a direct developer. Given its placement in the phylogeny (Min et al. 2005), the case for a reversal in *Desmognathus* is even stronger; argument against reversal now requires the independent evolution of direct development in at least six clades (*Plethodon*, *Hydromantes* + *Ensatina*, *Karsenia*, *Aneides*, *Phaeognathus*, and *Desmognathus wrighti*).

What has become clear in this developing debate is the absence of relevant comparative ontogenetic and developmental morphological data for salamanders. Relatively few species have been studied, and even such common species as members of *Amphiuma* are imperfectly known. Direct development is best known from studies of a species that is only a marginal direct developer, *Desmognathus aeneus* (Marks 2000), and very little is known about the early ontogeny of the 328+ species of direct developing plethodontids, many of which may prove to be relevant to this controversy.

Bruce (2005) presents provocative arguments in favor of an ancestral biphasic life-history mode for plethodontid salamanders, in particular for the genera formerly assigned to subfamily Desmognathinae Wake 1966: *Desmognathus* + *Phaeognathus*, the supergenus *Desmognathus* (sensu Chippindale et al. 2004). Bruce disputes the inferences of Chippindale et al. (2004) that a reversal from direct development to an aquatic larval stage occurred in *Desmognathus* (see also Bonett et al. 2005; Mueller et al. 2004). For decades, Bruce has played a leading role in studies of plethodontid life-history evolution (e.g., Bruce et al. 2000), and his disagreement with our conclusions is a cause for concern that must thoroughly be addressed.

The possibility that direct development is the ancestral state for supergenus *Desmognathus* (*Desmognathus* hereafter) has been discussed by several authors (e.g., Collazo and Marks 1994; Marks 2000; Titus and Larson 1996). The new and largely concordant phylogenetic hypotheses of Chippindale et al. (2004), Mueller et al. (2004), and Macey (2005) provide an opportunity to trace life-history evolution in plethodontids within a rigorous phylogenetic framework. Here, we address Bruce's arguments and show that the preponderance of evidence supports re-evolution of the aquatic larval stage in *Desmognathus*.

Bruce offers six key arguments in favor of biphasic development as the primitive condition for *Desmognathus*. We will address these in the order in which they appear in his paper. We

think that the issues can be distilled to four questions: (1) Is the family-level placement of plethodontids correct? (2) Is the phylogenetic position of supergenus *Desmognathus* within Plethodontidae correct? (3) Is the ancestral reconstruction for the evolution of direct development correct? (4) How strong is the evidence that competition in terrestrial environments drove the re-evolution of the larval stage?

1. The Sister Family Question: Amphiumidae or Rhyacotritonidae?

Bruce raises concerns about the phylogenetic position of Plethodontidae and the possible implications of its placement for the ancestral reconstruction of direct development in the family. Larson and Dimmick (1993) and Larson et al. (2003) showed relationships among amphiumids, plethodontids, and rhyacotritonids to be uncertain, and the analyses of Mueller et al. (2004) and Macey (2005) omitted amphiumids. However, the analysis of Chippindale et al. (2004) found strong support for the relationships (Rhyacotritonidae (Amphiumidae + Plethodontidae)). This result also has been strongly supported in a more recent analysis of higher-level salamander relationships based on molecular and morphological data (Wiens et al. 2005). We think that the phylogenetic position of plethodontids has now been resolved, and that Chippindale et al. (2004) used the appropriate outgroup relationships (based on inclusion of nearly all salamander families in their phylogenetic analyses) for their ancestral-state reconstructions.

Bruce favors biphasic development as the ancestral condition for plethodontids, based in part on a presumed close relationship between Plethodontidae and Rhyacotritonidae. The latter family occurs in mountain stream habitats in western North America, has aquatic larvae, and exhibits some other features similar to those in plethodontids (e.g., lung reduction). However, new molecular analyses and combined molecular and morphological analyses overwhelmingly support amphiumids as the sister group of plethodontids (Chippindale et al. 2004; Wiens et al. 2005).

In this section of his paper, Bruce also asserts that the ancestral state reconstructions of Chippindale et al. (2004) assume that Amphiumidae is biphasic. He states that "life-history modes in amphiumids approach direct development" (p. 108). This is a very reasonable view, especially given recent work by Gunzburger (2003). In fact, we presented and discussed ancestral state reconstructions in which amphiumids were treated alternately as biphasic and as direct developers. Both approaches yielded nearly identical results, with overwhelming support for a direct-developing ancestral *Desmognathus* using both maximum likelihood- and parsimony-based methods. In addition, treatment of amphiumids as direct developers supports the intriguing possibility (also suggested by analyses in which amphiumids were coded as biphasic) that direct development is the ancestral condition for Plethodontidae, and that there have been additional reversals to biphasic development in other lineages of plethodontids besides *Desmognathus*.

2 and 3. Morphological Homoplasy and Plethodontid Phylogeny: The Whole is Greater Than Some of the Parts

Bruce's sections 2 and 3 relate (directly or indirectly) to his concerns about the phylogenetic position of *Desmognathus* based on the incongruence of new molecular results with certain morphological characters. Bruce has informed us (pers. comm.) that he does not question our phylogenetic conclusions, and he does adopt our new taxonomy in his paper. However, his discussion of character evolution suggests that he questions our placement of *Desmognathus* within Plethodontidae, and we wish to clarify some of the issues that he raises.

A critical point is that simply discussing the evolution of selected morphological characters provides a very limited view of the implications of the morphological data for the phylogeny, at least relative to performing a full-scale phylogenetic analysis. Bruce fails to mention that Chippindale et al. (2004) performed a thorough phylogenetic analysis of the available morphological data for plethodontid phylogeny. This analysis included 123 morphological characters (including both original observations as well as characters based on data in the literature), encompassing nearly all of those discussed by Bruce (i.e., toe number, tongue structure, tail autotomy, and number of larval epibranchials, but not the presence or absence of lateral line organs). Rigorous analysis of the morphological data fails to support the traditional basal position for *Desmognathus* within Plethodontidae. Indeed, a basal position for *Desmognathus* was supported by only a single character (three larval epibranchials) in the widely used phylogenetic hypothesis of Lombard and Wake (1986). Furthermore, although the morphological analyses do not support the placement of *Desmognathus* within plethodontines as the molecular data do, they do not support monophyly of plethodontines either.

On the other hand, phylogenetic analyses of mitochondrial genome sequences (Macey 2005; Mueller et al. 2004), combined and separate analyses of nuclear and mitochondrial data (Chippindale et al. 2004), and combined molecular and morphological data (Chippindale et al. 2004) show that *Desmognathus* is nested within Plethodontinae (*Aneides* + *Ensatina* + *Plethodon* + supergenus *Desmognathus*, sensu Chippindale et al. 2004; Macey 2005 also included *Hydromantes* in this group). With the exception of the biphasic species of *Desmognathus*, all plethodontines are direct developers. At least two of the three direct-developing members of supergenus *Desmognathus* (*Phaeognathus hubrichti* and *D. wrighti*) appear to be basal to the remaining species; the third direct-developing species (*D. aeneus*) may be as well (Chippindale et al. 2004; Titus and Larson 1996; note that Mueller et al. 2004 and Macey 2005 did not include this species in their analyses). The data sets are not completely independent: Chippindale et al. (2004) included 1,473 mitochondrial characters in some of their analyses, overlapping with the 14,040 used by Mueller et al. (2004) and then reanalyzed by Macey (2005). However, it is noteworthy that none of the analyses support either a basal position for *Desmognathus* or monophyly of the former Plethodontini (*Plethodon*, *Ensatina*, and *Aneides*). Instead, the available data favor nesting of *Desmognathus* within an otherwise exclusively direct-developing clade of plethodontids.

4. Evolution of Direct-Developing *Desmognathus*: The Phylogeny Matters

In this section, Bruce discusses scenarios that might account for the evolution of direct development in genera *Phaeognathus* and *Desmognathus*. However, Bruce misses a key point. Given the overwhelming phylogenetic evidence that *Desmognathus* and

Phaeognathus are nested inside of plethodontines, any explanation for the evolution of direct development must also include *Plethodon*, *Aneides*, and *Ensatina* (and probably *Hydromantes* as well). Rather than making complex arguments to explain why direct development evolved convergently in these ecologically and morphologically diverse lineages, a simpler solution may be that this trait evolved in the common ancestor of all of these genera, and that there have been subsequent changes in body size, microhabitat specialization, and other traits among species sharing this developmental mode. This is what appears to have happened in the morphologically and ecologically diverse bolitoglossines, all of which are direct developers (Wake 1966). Thus, Bruce's comparison of miniaturization in the bolitoglossine genus *Thorius* to that in *Desmognathus aeneus* and *D. wrighti* merely highlights the repeated, extreme changes in body size in plethodontid lineages with direct development.

5. The Ecological Scenario: Out of the Frying Pan, into the Cool Mountain Stream

We speculated that competition with terrestrial plethodontids (likely *Plethodon*) drove the reinvasion of aquatic habitats and subsequent radiation of *Desmognathus* (note that in this section we refer only to members of the genus *Desmognathus*), whereas Bruce suggests that competition with aquatic salamanders may have led to repeated evolution of direct development. Our scenario is consistent with our likelihood-based analysis of divergence dates in plethodontids. Radiation of *Plethodon* in Appalachia appears to have predated or overlapped with the radiation of biphasic *Desmognathus*. Bruce counters with an "out of the frying pan, into the fire" argument, invoking possible competition with or predation by spelerpine (sensu Chippindale et al. 2004) plethodontids in Appalachian stream habitats. Spelerpinae is a subfamily corresponding to the tribe Hemidactyliini (Wake 1966), but excluding the phylogenetically distinct genus *Hemidactylium*.

Given that our hypothesis of competitive interactions was highly speculative, we do not have compelling evidence that competition with spelerpines may be less important to species of *Desmognathus* than competition with other plethodontines. However, some lines of evidence are suggestive of this idea. First, both spelerpines and *Desmognathus* seem to reach their maximum local species richness in streamside habitats (Petranka 1998), which is not the expected pattern if competition between them was substantial. Second, there is extensive microsympatry among many species of *Desmognathus* and spelerpines along streams in eastern North America (e.g., members of the *Eurycea bislineata* complex and *Gyrinophilus porphyriticus*), suggesting that these lineages can coexist without competitively excluding each other (Petranka 1998). In contrast, there is considerable evidence for competitive interactions among terrestrial plethodontines (e.g., Hairston 1996), and Hairston (1981) suggested that some stream-associated Appalachian plethodontids (including members of the genus *Desmognathus*) might escape competition for nesting sites with terrestrial *Plethodon* by breeding in or near aquatic habitats. Furthermore, recent evidence (Baldwin 2002, unpubl. data; Baldwin and Chippindale, unpubl. data) indicates that *Pseudotriton*, one of the spelerpine genera that is sympatric with *Desmognathus*, colonized the Appalachian highlands very recently, long after the radiation of biphasic *Desmognathus*.

6. Evolutionary Reversals and Breaking Dollo's Law: Crimes and Misdemeanors

Bruce rests much of his case on "Dollo's Law" (or "principle"), the assumption that complex characters, once lost, cannot re-evolve (or at least not in their original forms). However, there is abundant evidence that Dollo's Law has been broken repeatedly. One clear example is the re-evolution of teeth on the lower jaw of the hemiphractine treefrog *Gastrotheca guentheri* (Duellman and Trueb 1986). Other recent examples (while not without controversy) also show the loss and re-evolution of complex features, such as hind limbs in snakes (Tchernov et al. 2000), wings in stick insects (Whiting et al. 2003), and shell coiling in gastropod molluscs (Collin and Cipriani 2003). Given these challenges to the generality of Dollo's principle, we seriously question its applicability to plethodontid salamanders.

Recent advances in evolutionary developmental biology may explain why Dollo's Law may be broken so frequently. Numerous complex phenotypic traits appear to be controlled by regulatory or "master switch" genes (e.g., Carroll et al. 2001; Rogers et al. 2002; Wilkins 2001). These genetic control systems provide a potential mechanism by which expression of complex features may be turned off and then on again during development and over evolutionary time. Furthermore, based on analyses of mutation rates, Marshall et al. (1994) estimated that key genes controlling organismal structure and function can remain intact for millions of years, even if they are not expressed. It seems reasonable that gene reactivation or altered timing of regulatory gene expression could enable a return to a biphasic lifestyle in some plethodontids. We also question the extent to which invoking Dollo's Law is applicable in the case of *Desmognathus*, given that some larval traits may be expressed in the embryos of direct-developing plethodontids. For example, the embryonic hyobranchial apparatus of *Plethodon cinereus* retains key features associated with a larval lifestyle, albeit in a reduced form (Dent 1942). Thus, the reacquisition of the larval stage in *Desmognathus* may not require the re-evolution of all larval traits.

We agree with Bruce that more detailed study of development in plethodontids (using both embryological and molecular genetic approaches) would be valuable, given that most inferences about the morphology and development of embryos have been based on data from only a tiny fraction of the extant species, in the absence of a rigorous phylogenetic framework. However, we caution that the morphology of embryos and larvae may be subject to just as much homoplasy as the adult morphology, and may not be perfect indicators of the evolutionary history of traits or taxa (e.g., Wiens et al. 2005).

Bruce's Conclusions

Bruce concludes, in part, by stating that reconstruction of ancestral states on Macey's (2005) "total evidence" mitochondrial genome tree is consistent with a biphasic ancestral state for *Desmognathus*. However, we believe that his interpretation is in error with respect to simple parsimony. According to our calculations (using MacClade v. 4.02; Maddison and Maddison 2000), an ancestral *Desmognathus* with aquatic larvae requires a minimum of five steps on Macey's total-evidence tree (if all taxa are shown). If re-evolution of biphasic development within *Desmognathus* is allowed, then only three steps are required, mak-

ing this the more parsimonious hypothesis. We obtained an identical result using Macey's (2005) alternate, transversion-only parsimony tree. Furthermore, Mueller et al. (2004) and Macey (2005) examined only two of the three direct-developing species of *Desmognathus*, and excluded *D. aeneus*. This omission potentially biases their results against finding direct development to be ancestral within *Desmognathus*. Addition of *D. aeneus* to their analyses likely would require a sixth step for the ancestral *Desmognathus* to be biphasic, given the many other studies that indicate that this species is a basal member of the genus *Desmognathus* (e.g., Chippindale et al. 2004; Titus and Larson 1996). Thus, contrary to Bruce's conclusions, the most parsimonious explanation for the distribution of developmental modes in plethodontids requires a reversal to the aquatic larval stage in *Desmognathus* for all of the phylogenies discussed here.

Our Conclusions

Bruce (2005) has challenged our conclusions regarding the loss of direct development and re-acquisition of the larval stage in plethodontid salamanders. Specifically, he has raised doubts about (1) the phylogenetic placement of plethodontids within salamanders, (2) placement of the supergenus *Desmognathus* within plethodontids, (3) reconstruction of direct development as the ancestral state in *Desmognathus*, and (4) our ecological scenario for why this reversal has occurred. We have argued that the placements of plethodontids and the supergenus *Desmognathus* are very strongly supported by our analyses, and the contradictory morphological evidence mentioned by Bruce had already been taken into consideration. Furthermore, his argument against our ancestral reconstruction is based largely on a principle (Dollo's Law) that has been challenged both by new empirical evidence (e.g., Tchernov et al. 2000; Whiting et al. 2003) and a new understanding of the evolution and expression of regulatory genes (e.g., Carroll et al. 2001; Marshall et al. 1994). Our hypothesis that competitive interactions drove this evolutionary reversal is (admittedly) highly speculative, but no more so than the alternative hypothesis proposed by Bruce.

We conclude by posing the following question: what additional evidence would be required for Bruce to accept that there was re-acquisition of the larval stage in *Desmognathus*? Initially, we found this result hard to believe ourselves, and we even agree (in principle) that a few more independent origins of direct development might be more likely than a reversal. However, in the case of *Desmognathus*, the probability that repeated origins of direct development explains the phylogenetic pattern is extremely low. Given our maximum likelihood reconstructions on the tree based on combined nuclear DNA, mitochondrial DNA, and morphological data, multiple origins of direct development would have to be >77,000 times more likely than a single loss. We think that the available evidence points towards a loss of direct development and re-evolution of aquatic larvae as the more likely explanation. We invite Bruce (as one of the leading authorities on plethodontid life-history evolution) to identify what specific evidence could convince him of the veracity of our conclusion.

Acknowledgments—.We thank Richard Bruce for stimulating discussion and the opportunity to share points of view. Our research on plethodontid salamanders has been supported by NSF grants DEB-0129242, 0105115, and 0206730 (to PTC) and DEB-0129142 and 0331747 (to JJW).

Nomenclatural Notes on the Generic Nomen *Luperosaurus* Gray, 1845 (Squamata: Gekkonidae)

INDRANEIL DAS
Institute of Biodiversity and Environmental Conservation
Universiti Malaysia Sarawak
94300 Kota Samarahan, Sarawak, Malaysia
e-mail: idas@ibec.unimas.my

Gray (1845) occupied the nomen *Lyperosaurus* (p. 145, and later, on p. 283, in the index) and subsequently *Luperosaurus* (p. 163) for a genus of Southeast Asian gekkonid lizards. The root 'Lyper,' Greek for 'difficult' or 'vexing,' is presumably for sharing characters of *Amydosaurus* Gray, 1845 (synonymous with *Lepidodactylus* Fitzinger, 1843 and *Ptychozoon* Kuhl and van Hasselt, 1822). The type species of the genus is *Luperosaurus cumingii* Gray, 1845, by monotypy. The content of *Luperosaurus* has been reviewed by Boulenger (1885), W. C. Brown and Alcala (1978), Russell (1979), and R. M. Brown and Diesmos (2000), and the latter nomen appears in checklists compiled by Kluge (1991, 1993, 2001), Rösler (2000), Welch (1994), Welch et al. (1990), and Wermuth (1966), but none of these reviews or lists give reference to the other original spelling (*Lyperosaurus*) of the generic nomen. In the most recent checklist of constituent species of the genus, Kluge (2001) recognized eight species within the genus, including *Luperosaurus browni* Russell, 1979 and *Luperosaurus yasumai* Ota, Sengoku, and Hikida, 1996, from the Sundas, *Luperosaurus iskandari* R. M. Brown et al., 2000, from Sulawesi, and *brooksii* Boulenger, 1920, *cumingii* Gray, 1845, *joloensis* Taylor, 1918, *macgregori* Stejneger, 1907 and *palawanensis* W. C. Brown and Alcala, 1978, from the Philippines (Brown and Alcala 1978).

Although the lack of citation of the nomen *Lyperosaurus* by Boulenger (1885:181), in the next monograph of the lizard collection of the British Museum (Natural History) can be interpreted that the name is a *lapsus calami*, argument against include its inclusion on p. 283 of the index of the work by Gray (1845), which notes its usage on p. 163 (where it is spelled *Luperosaurus*). The manuscript of the original work does not exist at The Natural History Museum, London, and Gray's annotated copy of the printed work (kindly examined by C. J. McCarthy at my request) has no corrections or remarks concerning these nomina.

Article 24.2.3 of the International Code of Zoological Nomenclature (International Commission of Zoological Nomenclature, 1999, hereafter, The Code) states that if more than a single original spelling for the same taxon exists, the first author to cite them together can select one spelling as correct (the First Reviser Principle), whereupon the other original spelling is incorrect and therefore unavailable. No such selection has ever been made. In accordance with Article 24.2.3 and Recommendation 24a of The Code, which states that the selection should be the one that "best serves stability and universality of nomenclature," I here select, as First Reviser, the nomen *Luperosaurus* Gray, 1845 as valid for the taxon, instead of *Lyperosaurus*. The spelling *Lyperosaurus*, with this action and in conformance with that article, has no nomenclatural status.

Acknowledgments.— I thank A. M. Bauer, P. David, C. J. McCarthy, R. Pethiyagoda, and H. M. Smith for comments.

Variation in and Natural History Notes on *Tropidophis fuscus* (Serpentes: Tropidophiidae) from Cuba

ANSEL FONG G.
BIOECO, Museo de Historia Natural "Tomás Romay," Enramadas # 601
Santiago de Cuba 90100, Cuba
e-mail: ansel@bioeco.ciges.inf.cu

The Cuban snake *Tropidophis fuscus* Hedges and Garrido, 1992 was described from two specimens from Minas Amores (Baracoa municipality) and Cruzata (Yateras municipality), both in Guantánamo Province, eastern Cuba (Hedges and Garrido 1992). Until now, this species has been included only in checklists (Powell et al. 1996; Estrada and Ruibal 1999; Fong and Navarro 2001) and in range extension notes (Fong 2000, 2002). Because of the rarity of this species, herein I report new data on the seven specimens included in those range extensions, all of which have been deposited in the herpetological collection of BIOECO in Santiago de Cuba (BSC.H) and "Carlos de la Torre" Natural History Museum in Holguín (MHNH). Data on localities, dates of collection, and collectors of these specimens have been published elsewhere (Fong 2000, 2002).

Specimens from El Toldo plateau, northeastern Cuba (Fong 2000), were collected by day, coiled under stones, where they were apparently inactive; one male (BSC.H 2026) was partially underground. This locality is a mixture of pine forest (*Pinus cubensis*) and broadleaf woods growing in a red lateritic soil, similar to the type locality (Hedges and Garrido 1992). The specimen from Sabana, Guantánamo Province (Fong 2002) was collected under a fallen tree trunk along the edge of a coffee plantation in a semideciduous woodland.

Two captive specimens underwent color changes similar to those observed in other species of the genus (Hedges et al. 1989; Rehák 1987). This was not observed in the type specimens, perhaps due to their brief time in captivity (Hedges and Garrido 1992). At night and with lights off, the two snakes were very light, almost gray, with very dark dorsal blotches. During the day or with lights on, the snakes had the dark coloration described for the type specimens (Hedges and Garrido 1992). When first captured, all individuals showed this dark pattern.

The new material of *T. fuscus* conforms well with the meristic and morphometric characteristics of the type specimens (Table 1), except that they expand the range of postocular scale numbers (from 3 to 2–4), subcaudal scale numbers (from 32 to 30–36), and dorsal rows of blotches (from 8 to 6–8, although only one specimen had six rows).

As in other species of *Tropidophis* (Schwartz and Marsh 1960), males of *T. fuscus* have one spur on each side of the vent. Females lack these spurs and tend to be larger than males. Except for MHNH w/n (original number AFG 369), the other two males have shorter snout-vent lengths than the two females (Table 1). The female holotype remains the largest known specimen. Males tend to have longer tails (14.5–17.8% of SVL) than females (11.2–11.6% of SVL), in contrast with the difference in SVL.

The female I collected was maintained in captivity and gave birth on 12 October 1996 to three neonates (BSC.H 750–752). The female weighed 7 g immediately after parturition, whereas the neonates weighed 0.75 g each. Measurements and counts of the young are given in Table 1. The only data about reproduction are those given by Hedges and Garrido (1992), who noted that the holotype (MNHNCU 2705) contained four or five well-developed young (they could not determine the exact number).

The neonates have a similar coloration pattern to that of the adults, except that the dorsal body blotches are surrounded by a few faint whitish scales (not present in adults), tail tips are bright yellow (no differently colored than body in adults), tops of the heads are brownish yellow (uniformly dark brown or black in

Table 1. Measurements (in mm), counts, and proportions of *Tropidophis fuscus*. Data for the holotype and paratype are from Hedges and Garrido (1992). All specimens with dorsal scales weakly keeled and parietal scales not in contact. F = female, M = male, J = juvenile, SVL = snout-vent length, TL = tail length, V = ventrals, S = subcaudals, SL = supralabials, IL = infralabials, P = preoculars, O = postoculars, DS = dorsal scales, DB = dorsal body blotches, LR = longitudinal rows at midbody, ED = eye diameter, HW = head width, NW = neck width.

* Holotype, ** Paratype

adults), and two large white occipital spots fuse to form white collars, which are much more prominent and visible than those of adults. This pattern is similar to that seen in adult *T. pilsbryi*, suggesting affinities with that species. Schwartz and March (1960) recorded a radical ontogenetic change in the pattern of Bahamian *Tropidophis* (*canus, curtus, androsi,* and *barbouri*), from heavily spotted with dark blotches on a lighter ground color in juveniles to less prominent and faintly spotted in darker adults. A similar pattern apparently applies to *T. fuscus*.

Acknowledgments.- I thank my colleagues in the biodiversity monitoring program in El Toldo plateau for field assistance, especially Gabriel Garcés, Leopoldo Viña, and Angel Luis Machín. I also thank S.B. Hedges for sending useful literature, as well as R.W. Henderson, R. Powell, and an anonymous reviewer for comments on an earlier draft of this manuscript.

e-mail: heyerr@si.edu

Most species of the frog genus *Leptodactylus* lack common names. Common names are those names used by different human cultures and societies for the species of animals and plants where humans and biota reside together. Often times common names are lacking for Neotropical frogs or are broad in scope. For example, indigenous people may have a single name for frogs that occur on the ground and another name for frogs that occur in shrubs and trees, even though there are many species of ground frogs called by the same name as well as for the tree frogs. Sometimes colonists have used the same names as indigenous peoples, but often colonists use different names (usually imported from their own geographic origin), as they did not understand the indigenous word or words involved. Therefore, there may be different names used by humans for the same frogs at the same places—this is particularly true when more than one language or dialect is spoken in a given geographic area.

Why Use Common Names?

The simplest solution for what names to use for frogs would be for everyone to only use scientific names. In fact, this is the approach we have espoused and still recommend. However, it is clear that outside the systematic scientific community certain organizations only use or require common names for animals and plants; furthermore, they will continue to do so. For example, evaluation of the United States form 3-177 for importation of specimens into the US is based on common names, not scientific names, even though there is space for both kinds of names on the forms. Several ecotourism guidebooks only use common names. Many scientific journals only include common names in the titles of the articles. Common names are in use and will continue to be used.

Our purpose is to develop a standard set of common names (and their geographic synonyms) for the frog genus *Leptodactylus* for individuals who wish to use common names for *Leptodactylus* species.

Criteria for Evaluating Common Names

We find the literature on common names for *Leptodactylus*

species to be fragmentary, obscure, and/or inappropriate. For example, most of the names proposed by Frank and Ramus (1995) are inappropriate, inane, or both. As one example, they proposed Tropical Bullfrogs as the common name for the genus *Adenomera* and used Tropical Bullfrog in each of the common names for the recognized species in the genus. Members of the genus *Adenomera* are primarily tropical in distribution. However, none of the species is either large or has calls that sound like bulls (cattle). All but one species are less than 30 mm in snout–vent length; *Adenomera lutzi*, the largest species, only reaches 34 mm SVL. All species for which calls are known have different kinds of very short, high-pitched whistles.

The criteria we use for choosing the name to become the standard common name for each of the species of *Leptodactylus* are in priority order and are exclusive (that is if the first criterion can be used, it will be applied without consideration of the remaining criteria).

1. Any name that is in use and has been well established (i.e., most frequently used and appropriate) in publications. At times, the name that follows this criterion could be different than the name used locally.
2. The intent of the person who described the frog should be used, either explicitly or implicitly through use or translation of the scientific name.
3. Use of some distinctive aspect of the species including its distribution.

There are additional considerations for choosing among alternate names within the above criteria. These criteria are much more subjective and serve only as guidelines and can not be applied consistently.

- If a species occurs exclusively or primarily in Brazil, the Portuguese name is the name used to translate into English and Spanish. If the species occurs exclusively or primarily in Spanish-speaking countries, the Spanish name is the name used to translate into English and Portuguese.
- Common names should be distinguishable from all other common names at least in the Western Hemisphere and preferably worldwide. The proposed common name Chaco Frog for *Leptodactylus chaquensis* rather than Chaco Thin-toed Frog is preferred because the species involved has been called Rana Chaqueña in Argentina and will not be confused with any of the other species of frogs that occur in the Gran Chaco. On the other hand, the proposed name for the taxonomically unstable *Leptodactylus ocellatus* is Common Thin-toed Frog, rather than Common Frog, as the latter means the European *Rana temporaria* to many individuals.

How the List of Common Names Works

The list of common names is maintained on the web site http://learning.richmond.edu/Leptodactylus. Individuals are encouraged to participate in the process of determining the standard common names through sending comments and additions to us via the web site. We will use this information to update the site on a regular basis and acknowledge all individuals whose contributions are incorporated.

Each entry is headed by the scientific name. Only names currently recognized as valid are included. English, Portuguese, and Spanish names are listed for each species. If there is not a currently standardized common name in use, the title "Proposed (English, Portuguese, Spanish) name" is used. Once a consensus emerges, the word "proposed" will be dropped from the title.

As we have exercised our judgment on what common names should be considered as standard names for the first list, we also invite and welcome initial discussion on whether other names are more appropriate than those we have selected.

Each entry also has a list of other names that have been used in the literature or are used regionally for the species involved. We solicit additions to these entries as we have made no effort to extensively survey the literature for common names for *Leptodactylus* and are not aware of all names in local use.

When called for, comments are included for an entry.

The bibliographic citations are maintained in a separate file on the web site.

The Genus *Leptodactylus* as an Example

We find no published common name for *Leptodactylus* to be appropriate. Frank and Ramus (1995) used White-lipped Frogs as the common name for the genus. However, most species of *Leptodactylus* do not have white lips, making this name non-inclusive and misleading. Whistling Frogs is another name that has been used for the genus, but again, not all species of *Leptodactylus* have calls that sound like whistling. Fitzinger's name *Leptodactylus* is derived from the Greek words *leptos* (thin) and *daktylos* (finger or toe). This condition strictly applies to all but a few species of *Leptodactylus*. The few exceptions have small expanded disks at the tips of the toes, which are narrow or thin in comparison to most tree frog toes (e.g., Centrolenidae, Hylidae) or the expanded overall triangular disks found in most species of *Eleutherodactylus*. Therefore, we propose that the standard common name for the genus *Leptodactylus* should follow the second criterion and be known as Thin-toed Frogs.

The family Gekkonidae is well known for having a number of highly effective colonizing species that have broadly expanded their distribution, invaded geographically distant places and have become human commensals, with or without deliberate human help (Lever 2003; Meshaka et al. 2004). Among the most accomplished invasive species are certain members of the genus *Hemidactylus*. This genus comprises around 80 recognized species (Bauer and Pauwels 2002), which are distributed throughout Africa, southern Europe, southern Asia, Polynesia, Oceania, and the Americas (Avila-Pires 1995; Lever 2003; Savage 2002). Although some of the nine New World taxa appear to be native to South America and the Caribbean (*H. agrius*, *H. haitianus*, *H. leightoni*, and *H. palaichthus*), the remainder (*H. brooki*, *H. frenatus*, *H. garnotii*, *H. turcicus*, and *H. mabouia*) are certainly present in the Americas due to accidental introductions from their native ranges in the Old World. Of these, the Tropical House Gecko, *H. mabouia* (Fig. 1–2) is the most broadly distributed, occurring in southeastern Florida, the West Indies, Trinidad and Tobago, the Gulf Coast of México (Veracruz), Honduras, and Panama (Köhler 2003; Powell et al. 1998). In South America, it ranges from Venezuela and the Guianas through coastal Brazil and into the Amazon basin in the latter country, Colombia, Ecuador, and Peru. It has also been recently reported in Argentina (Avila-Pires 1995; Federico and Cacivio 2000; Malhorta and Thorpe 1999; Powell et al. 1998; Rivas et al. 2001).

The known *Hemidactylus* fauna of Venezuela includes *H. palaichthus*, *H. leightoni*, and *H. mabouia* (Kluge 1969; La Marca 1997; Rivas et al. 2001; Rivas 2002; see Powell et al. 1996 and Rivas 2002 for remarks regarding the status of the taxa formerly regarded as subspecies of *H. brookii*). At present, the Tropical House Gecko (*H. mabouia*) is not only the sole introduced gecko recorded from Venezuela, but also the most common nocturnal lizard in many of the towns and cities in the northern portion of the country. The documentation of the expansion of *H. mabouia* is particularly important as this lizard has been shown to be an aggressive species (Zamprogno and Teixeira 1998) capable of displacing other geckos (Meshaka et al. 2004), and could very well cause the decline or even the disappearance of some native lizards, particularly other geckos. Until now, the distribution of *H. mabouia* in Venezuela has been limited to perianthropic situations, where it occurs with a wide variety of native species of lizards, including the geckos *Gonatodes albogularis*, *G. ceciliae*, *G. falconensis*, *G. vittatus*, two undescribed species of *Gonatodes*, *Hemidactylus palaichthus*, *Phyllodactylus rutteni*, *P. ventralis*, and *Thecadactylus rapicauda*. These taxa could be greatly affected by competition from the highly adaptable *H. mabouia*. We herein report a series of new localities for *H. mabouia* in northern Venezuela, documenting the expanding range of the taxon, and provide some data on the reproduction and habits of this gecko in the country, as well as some comments on the apparent impact this species has had on the populations of two other, native gecko species. We also document for the first time the occurrence in Venezuela of another introduced gecko, *Hemidactylus frenatus*.

In documenting the occurrence of introduced *Hemidactylus* in Venezuela, we have generally relied on voucher specimens (or occasionally voucher photographs) deposited in museums. Museum abbreviations used are as follows: EBRG – Museo de la Estación Biológica de Rancho Grande, Maracay, MBUCV – Museo de Biológia de la Universidad Central de Venezuela, Caracas, MCNC – Museo de Ciencias Naturales de Caracas, Caracas, MHNLS – Museo de Historia Natural La Salle, Caracas, and MBLUZ – Museo de Biologia de la Universidad del Zulia, Maracaibo. However, in certain cases, we have also accepted reliable sightings that have been verified by more than one source (Kaiser et al. 2002). Such records may be of particular importance, as common species, like *H. mabouia*, often are overlooked by scientists and, paradoxically, may not be collected because of their ubiquity and abundance. Therefore, such a species can be

quite common in a locality for a long period without ever being reported, leaving considerable gaps in our knowledge of the expansion and total distribution of an exotic taxon.

Expansion in Venezuela—The known distribution of *H. mabouia* in Venezuela includes 13 states plus the Distrito Capital of Caracas and extends across almost all of the northern part of the country (Table 1). Despite this, only very recently has the extent of the species' distribution in the country been clarified and documented (Rivas et al. 2001). It was first reported from Venezuela by Burt and Burt (1931) and Parker (1936) from La Esmeralda and the upper Orinoco, respectively. These records (and Vanzolini's citation of them in 1968) actually represent *H. palaichthus,* a native species, which was not described until later (Vanzolini 1978). *Hemidactlyus mabouia* was next reported in northern Venezuela by Lancini (1962) from Isla de Patos, Sucre on the basis of a single, young individual. However this specimen (cited as MCNC 2330) is not present in the MCNC collection and the voucher number belongs to another species (L. F. Navarrete, pers. comm.). Years later, Donoso-Barros (1968) also reported this species for Venezuela, indicating localities in the state of Sucre, including one from Isla de Patos (based on Lancini's report). His records from Yacua, Puerto de Hierro, and Macuro were subsequently considered referable to *H. palaichthus* by Vanzolini (1978). We did not locate Donoso-Barros' vouchers, at least in any Venezuelan collections examined. Vanzolini (1978) mentioned some additional Venezuelan *Hemidactylus* records of undetermined specific identity, including one from the Andean slopes in Barinas. This record is almost certainly referable to *H. palaichthus*, which was subsequently verified for that region by Markezich (2002). However, another of his records, from the central coastal range (La Guaira, Vargas State), could very well be *H. mabouia*, whereas geckos from the eastern coastal range in the state of Sucre (Cumaná and

Cumanacoa) could be either *H. mabouia* or *H. palaichthus*, both of which are found in that state.

Rivas and Oliveros (1997) indicated the presence of *H. mabouia* for areas neighboring the city of Cumana, Sucre (Cerro Colorado and Cerro La Malagueña). However, their vouchers are actually misidentified individuals of *H. palaichthus,* as we suspect were those mentioned by Donoso-Barros (1968) and Oliveros et al. (2000). However, Rivas and Oliveros (1997) did correctly identify a specimen from Tunapuy, Sucre to *H. mabouia*, thereby providing the first reliable documentation of the species in Venezuela. Subsequently, Mijares-Urrutia and Arends (2000) reported the species from the northwestern portion of the country in Falcón State, and Rivas (2001) and Rivas et al. (2001) reported a few more verified localities. A record of this species exists for Guayacán, Peninsula de Araya, Sucre State (Cornejo and Prieto 2001), but we were unable to examine the single individual and therefore consider this record unverified.

Hemidactylus mabouia in Venezuela appears to have expanded from Caracas, where it has been present for at least ten years (Rivas 2001), both toward the east and the west. It has expanded throughout major cities and maritime ports in the country. So far, this gecko has only been found in perianthropic areas and does not appear to penetrate non-disturbed locations. Reasons for the failure of *H. mabouia* to proliferate away from edificarian situations in Venezuela are unknown, but the species appears to have the same problem expanding to undisturbed habitats throughout its range. To the present, *H. mabouia* has been recorded in Venezuela widely distributed among coastal cities and towns from Sucre to Zulia states (including Margarita Island). It is found on the central slopes of the Cordillera de La Costa, in the Cordillera del Interior, and in the mountainous system of the states of Lara and Falcón in the Andean foothills, but always in human habitations and below 1000 m asl (Fig. 3) (Rivas 2001; Rivas et al. 2001; this paper).

Natural History—In Venezuela, *Hemidactylus mabouia* is commonly found in buildings and houses at heights up to 10 m. At night, it is active on either external or internal walls, whereas during the day, it hides in wall crevices, holes, wall hangings, under roof tiles, or under other objects leaning against walls. Occasionally, it can also be observed at the base of palms or other trees, but always in or near to perianthropic areas. It is predominantly nocturnal; however, in El Placer, near Caracas, the second author observed several adults active during the morning hours on overcast days. Limited diurnal activity has also been observed in the introduced populations in Florida (Meshaka et al. 2004) and the Lesser Antiles (Malhotra and Thorpe 1999). Individuals are frequently observed in search of insects around artificial lighting. In Ocumare de la Costa, Aragua, as many as four individuals were seen by the second author around a single light engaging in strong antagonistic behavior. Opponents first slowly waved their tails and then quickly approached each other, biting each other on the neck or

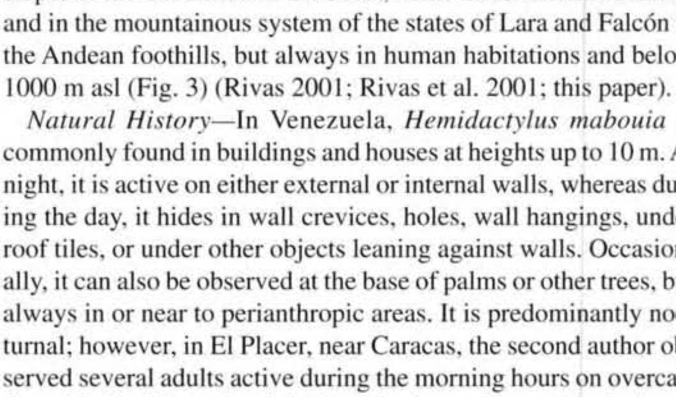

FIG. 3. Distribution of the introduced species of *Hemidactylus* (*H. frenatus* = asterisks, *H. mabouia* = solid dots) in Venezuela based on this study. Localities: 1) Sinamaica; 2) Maracaibo; 3) Urb. El Prado; 4) Barquisimeto; 5) La Vela de Coro; 6) Sanare; 7) Marín; 8) San Carlos; 9) Bahia de Patanemo; 10) Ocumare de la Costa; 11) El Limón-Maracay; 12) Tanaguarenas; 13) Distrito Capital records; 14) Urb. El Placer; 15) Los Naranjos-Guarenas; 16) El Morro, Puerto La Cruz; 17) Porlamar; 18) Tunapuy; 19) Carupano.

limbs, at times maintaining their grasp for more than a minute. Sometimes, a low, chirping sound was emitted by the bitten individual. When handled, some specimens produce a series of low, chirping sounds.

Hatchling and juvenile *H. mabouia* are strongly terrestrial when compared with adults. They are commonly found under rocks, rotten or fallen logs, piles of garbage, building materials, planks, and beneath the loose bark at the base of trees. Such sites conserve and radiate heat absorbed during the day (Howard et al. 2001) and may be thermally beneficial to young *H. mabouia*. Terrestrial retreats may also help juveniles to minimize the risk of predation by avoiding the climbing adults, which are known to be cannibalistic (Zamprogno and Texeira 1998), as well as other predatory lizards (Howard et al. 2001).

On 10 March 2001, the first and the fifth authors found five semi-spherical, calcareous eggs of *H. mabouia* inside tunnels dug by beetles in a rotten log in the areas surrounding the Instituto de Zoología Agrícola, Facultad de Agronomía de la Universidad Central de Venezuela, Maracay, estado Aragua (10°16'19"N, 67°36'34" W). The eggs, which measured 8.8–9.5 mm x 8.2–8.6 mm (N = 4), were incubated on parts of the log inside a clay vase. Two geckos hatched after 18 days at air temparatures of 27–32°C and were measured four days after eclosion (snout–vent length/tail length): 20.15 mm/19.02 mm (EBRG 3889); 19.52 mm/18.44 mm (released). These measurements are slightly smaller than those reported for African populations (Loveridge 1947), but similar to those from Colombia (Bock 1996), the West Indies (Malhotra and Thorpe 1999; Schwartz and Henderson 1991), and Florida (Meshaka et al. 2004). Communal egg sites have also been identified in buildings. On 15 October 2003, in the home of the first author (city of Caracas), 11 eggs and 30 empty shells of *H. mabouia* were found behind the cover of an electrical outlet. At least two females had been seen in that same area over the last four years.

Interspecific Interactions—The Tropical House Gecko has been introduced in areas with many species of native gekkonids in Venezuela. In the town of Ocumare de la Costa, Aragua, it is sympatric with *Gonatodes vittatus* and *Thecadactylus rapicauda*. The latter is a much larger, robust gecko, whereas the former is a smaller, diurnal sphaerodactyline gecko. The three species seem to be common in the area (at least when observed five years ago); however, all three taxa seemed to have well demarcated ecological niches. Adult *H. mabouia* were seen only on walls and other man-made structures, whereas *T. rapicauda* was mostly found in trees and on high roofs. In Ocumare de la Costa, Aragua, *T. rapicauda* appeared to be less common than *H. mabouia*, and competitive exclusion between these two species may occur. Competition between these two taxa was also suggested by Howard et al. (2001) on the West Indian island of Anguilla.

Many perianthropic situations in which *H. mabouia* is found in northern Venezuela are also occupied by *Gonatodes vittatus*. Although no quantitative data are available, the first two authors believe that *G. vittatus* has declined considerably in some areas of Caracas where it was very common several years ago, whereas the *H. mabouia* population has grown noticeably, indicating the possibility of predation of *G. vittatus* by *H. mabouia* or competition between the two species. The Tropical House Gecko is known to be cannibalistic (Zamprogno and Teixeira 1998), which could make it possible for this species to prey not only on their own young but on young or even adult individuals of the much smaller *G. vittatus*.

Hemidactylus frenatus—Rivas (2002) reported the first Venezuelan record of *Hemidactylus leightoni* based on material from Sinamaica, Zulia State (MHNLS 15574, EBRG 3786). A reevaluation of this material revealed that these specimens represent the Indo-Pacific House Gecko, *Hemidactylus frenatus*. Since its initial collection in 2000, this species has been found and observed to be common in urban areas throughout the northern half of the state of Zulia (Municipios Maracaibo, Mara, Paez, Almirante Padilla, among others; see Table 1). According to inhabitants of Maracaibo, this gecko has been present for at least 10 years, and local densities have increased dramatically during that time.

Venezuelan populations of *Hemidactylus frenatus* and their effects on native geckos are now being studied. Populations of native gekkonids, like *Gonatodes albogularis albogularis* and *Phyllodactylus ventralis*, apparently are declining in the presence of the invasive species. *Hemidactylus frenatus* also appears to be responsible for a decrease in cooccuring *H. mabouia*. Interestingly, in the Florida Keys, where both species occur, *H. mabouia* has proved to be the more successful, and populations of *H. frenatus* have diminished notably in the course of four years (Meshaka et al. 1994, 2004). The nature of the interactions between these two *Hemidactylus* are unknown, but *H. frenatus* has been known to competitively exclude a variety of other gecko species, chiefly parthenogenetic forms, in areas where it has been introduced (Bauer and Sadlier 2000; Petren and Case 1996; Petren et al. 1993), and in Veracruz, México it has been implicated in the displacement of *H. mabouia* (Powell et al. 1998).

Acknowledgments.—We thank J. Celsa Señaris for preparing the drawings and Fernando Rojas and César L. Barrio for providing distribution records.

Predation on a Fanged Frog (*Limonectes kuhlii*) by a Freshwater Crab (*Candidiopotamon rathbuni*)

HIROSHI TSUJI*

Department of Biology, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558-8585, Japan

**Present address: Department of Human Science, Baika Women's College Ibaraki, Osaka 567-8578, Japan*
e-mail: htsuji@baika.ac.jp

Adult frogs are common prey for a great variety of predators, including mammals, birds, reptiles, fishes, insects, and spiders, because they are abundant at breeding sites, small in size, and have soft skin (Duellman and Trueb 1994). Freshwater crabs also seem to be important predators on small frogs (Duellman and Trueb 1994) because they often coexist in riparian environments. However, reports of the predation on frogs by crabs are scarce (Duellman and Trueb 1994; Murphy 1997), and there is little quantitative information on the interaction between frogs and predatory crabs.

Limonectes (*Rana*) *kuhlii*, one of the fanged frogs which are characterized by a suite of unusual sexually dimorphic traits (males have larger body, head, and fang sizes than females), is a common ranid small-sized frog, occurring widely throughout Southeast Asia (Emerson 2001; Inger 1966; Pope 1931). *Limonectes kuhlii* from Taiwan is found throughout the year in shallow, slowly flowing waters of small streams or creeks with overgrowing grass in mountain regions (Yang 1998). Although the frogs are capable of reproduction throughout most of the year (Yang 1998), breeding activity peaks in summer in subtropical northern Taiwan (unpubl. data). Both adult males and females of *L. kuhlii* frequently appear at breeding sites along creeks (Tsuji 2004; Tsuji and Lue 2000); therefore the frogs may be attractive prey for predators. However, there is no available information concerning predation on *L. kuhlii*. I here report predation by a freshwater crab (*Candidiopotamon rathbuni*) on *L. kuhlii* from Taiwan, based on field observations during a three-month period.

Study site.—This study was conducted at Hsingsien near Wulai (24°52'N, 121°33'E; 150 m elev.), ca. 25 km S of Taipei in northern Taiwan, Republic of China. The study site is a small creek below a forested cliff. This creek flows permanently, despite being only 30–50 cm wide and 0.5–2.0 cm deep. The creek bed consists of gravel and mud covered with fallen leaves, and it is mostly shaded by ferns. An 81-m long transect, marked every 1-m section, was laid out along this creek.

Methods.—Field observations were conducted along a study transect from 1900 h until 2400–0300 h each night, on 50 nights from 12 June to 31 August. Censuses, for identifying the position of individual frogs, were carried out along the study transect sev-

4	7/2	00:55	7*	Pair	F1 (49.8), M12 (59.6)	Approach	
5	7/15	19:15	73*	Single	(M)M24 (57.4)	Attack	The crab attacked the frog twice in succession.
6	7/23	20:36	8*	Pair	F3, M25 (40.0)	Approach	
7	7/24	23:07	33*	Pair	F6 (57.9), M13 (59.6)	Approach	I moved the crab away from the pair.
8	7/25	22:39	3*	Single	(M)M2	Capture	The crab seized the frog's toe.
9	7/31	20:23	49	Single	(M)M8 (51.5)	Attack	
10	7/31	23:24	7*	Pair	F9 (50.0), M13	Approach	The crab approached the pair twice in succession.
11	8/14	20:50	75	Single	(F)F15[b] (48.0)	Capture	The crab was eating the frog's leg (see Fig. 1).

[a] ID no. of the male was unknown (apparently smaller than the amplectant female).

[b] The maturity of this female was unknown, because she never showed breeding behavior during the study period, although her SVL (48.0 mm) exceeded the minimum SVL (41.2 mm) of breeding females in this population (Tsuji and Lue 2000).

eral times each night. Observations were made using a 4.5-volt battery headlamp that did not seem to disturb the behavior of frogs and crabs.

In each encounter between frog(s) and crab, the time, the status of frog (single or amplectant pair), the identification number of the frog, its position along the transect (represented as section number), and the behaviors of frog and crab were recorded. The behaviors of crab were classified into three grades: "approach" (slowly walking toward a frog[s] at a distance of less than about 10 cm), "attack" (rushing at a frog[s] at a distance of less than about 5 cm), and "capture" (nipping a frog with a claw[s]). For several encounters in which an amplectant pair was targeted, I moved the crab away from the pair, in order to avoid disturbing the pair. When I found a frog captured by a crab, I released the frog from the crab after brief observation.

The body size (snout–vent length, SVL) of each frog was measured to the nearest 0.1 mm using slide calipers. The marking technique for permanent and temporary identifications and methods for checking the sex and sexual maturity of frogs are described elsewhere (Tsuji and Matsui 2002). Although I failed to measure the carapace width of *C. rathbuni* observed, it was about 4–5 cm.

Results.—A total of 11 encounters between *L. kuhlii* and *C. rathbuni* were observed during the 50 nights surveyed (Table 1). Frog-crab encounters occurred intensively in July (8 of 11 encounters; 72.7%). The number of encounters per survey night were 0.22 in June, 0.38 in July, and 0.05 in August (total = 0.22). Frog-crab encounters occurred in a wide range of the study transect (Table 1), but mostly in the sections with oviposition sites (81.8% of 11 encounters).

In 6 encounters (54.5% of 11), amplectant pairs were involved; in 4 pairs (66.7% of 6), the male was larger than the female (Table 1). Single males and females were involved three and two times, respectively. All targeted frogs were adult, except for female F15 (observation #11).

In the behavior of *C. rathbuni*, the frequencies of "approach," "attack," and "capture" were 6 times, 2 times, and 3 times, respectively (Table 1). When the frog(s) were approached or attacked by a crab, they jumped off, and the crab usually did not pursue them. In three encounters, however, the same frog(s) were targeted twice

FIG. 1. *Candidiopotamon rathbuni* eating the leg of a female *Limonectes kuhlii* (obs. no. 11 of Table 1).

during the same night (observations #1, #5, and #10).

I observed a crab capturing *L. kuhlii* 3 times (27.3% of 11 encounters), including 2 females and 1 male (Table 1). A female (F3) in observation #2 encountered a crab as amplectant pair (observation #1) at 0125 h and 0140 h, and she was observed being captured by her leg by a crab at 0158 h. A male (M2) in observation #8 was observed being captured his toe by a crab, emitting a distress call. A female (F15) in observation #11 was observed in the process of having her leg eaten by a crab (Fig. 1).

Snakes were observed 15 times at the study transect; they may have been predators of *L. kuhlii*. Fourteen of these observations involved the Red Banded Snake (*Dinodon rufozonatum*), and one snake could not be identified. However, I never observed a snake capturing a frog, or any type of frog-snake interactions.

Discussion.—These results suggest that crabs might be more important predators than snakes for *L. kuhlii*, because I observed crabs, but not snakes, attacking frogs. At present it is unknown whether the crabs kill the frogs in order to eat them, because I intervened and released the frogs captured by crabs in this study.

Predation by crabs on adult frogs may be common for small-sized frogs inhabiting the water's edge along small streams. A crab has been observed to be grasping the foreleg of *Colostethus ingunalis* in Panama, and many frogs of this genus that live along streams inhabited by crabs are missing limbs (Duellman and Trueb 1986). In Borneo, the frequency of the missing digits and limbs is significantly higher in *L. kuhlii* sitting closest to the water's edge than in any other species of frogs living along forest streams, presumably due to the predation by crabs (R. F. Inger, pers. comm.). Also in my study population, 4 (7.7%) of 52 adult frogs marked were missing a foot (unpubl. data).

The predation on adult *L. kuhlii* by *C. rathbuni* may be associated with the unique morphological features of this frog species. It may not be easy for a crab to capture an adult frog with its claw(s) because adult frogs usually exhibit good jumping performance. However, *L. kuhlii*, with its short hind legs, is not a strong jumper, even in adults. In addition, because the amplectant pairs (especially with the male being larger than the female) of *L. kuhlii* are more inactive (Tsuji and Lue 1998), they may be at greater risk of being attacked by crabs. Actually, in 6 (54.5%) of 11 frog-crab encounters, the amplectant pairs were targeted (Table 1); the pairs attacked by crabs accounted for 17.6% of the 34 pairs observed during the study period. Predation on amplectant pairs by crabs has been observed in *Physalaemus pustulosus* in Trinidad and Tobago (Murphy 1997).

The results of this study suggest several questions for the predator-prey interaction system of *L. kuhlii* and *C. rathbuni*: 1) what cues (visual, auditory, olfactory, or tactile) do *C. rathbuni* use for hunting *L. kuhlii*?; 2) what antipredatory mechanisms against the predatory crabs *L. kuhlii* have evolved?; and 3) how has the predatory behavior of *C. rathbuni* affected the life history and mating system of *L. kuhlii*? Because interactions between frogs and crabs are relatively easy to observe in the field, and because it should be possible to investigate experimentally crab-frog interactions in the laboratory, frogs and crabs might be ideal subjects for the study of predator-prey interaction.

Acknowledgments.—I am grateful to R. F. Inger for encouraging me to prepare this paper, and H. K. Voris and J. C. Murphy for kindly providing valuable literature citations. I also thank D. R. Karns and two anonymous reviewers for helpful comments on the manuscript. Special appreciation goes to J.-S. Lai for providing the scientific name of the crab, and K.-Y. Lue, Y.-S. Lin, P.-S. Yang, Y.-J. Yang, and M.-C. Su for their support with various aspects of field works in Taiwan.

Lack of Parasitism on Diamondback Terrapins (*Malaclemys terrapin*)

RALPH E. WERNER
Richard Stockton College of New Jersey
Pomona, New Jersey 08240, USA
ralph.werner@stockton.edu

The Diamondback Terrapin (*Malaclemys terrapin*) is the only turtle in North America to spend its entire life in salt marshes. Diamondback Terrapins are found along the East Coast from Massachusetts to Florida and along the Gulf Coast of Florida to Texas. Seven subspecies of *M. terrapin* have been described: *M. t. terrapin* from Massachusetts to North Carolina; *M. t. centrata* from North Carolina to Florida; *M. t. tequestra* on the east coast of Florida; *M. t. rhizophorarum* in the Florida Keys; *M. t. macrospilota* from southern and western Florida; *M. t. pileata* in Mississippi; and *M. t. littoralis* in Louisiana and Texas (Ernst et al. 1994). In the early 1900s, *M. terrapin* was nearly hunted to extinction for food. Although it is still harvested today in some areas, the U. S. Fish and Wildlife Service has placed the Diamondback Terrapin on its Candidate Species List (Burger and Garber 1995). This designation calls for studies to determine whether or not *M. terrapin* is endangered or threatened. In recent years, a resurgence of turtle consumption (Garber 1990a; Orenstein 2001) combined with mortality due to crab traps (Garber 1990b), oil spills (Burger 1994),

Table 1. Distribution of sample populations, subspecies of *Malaclemys terrapin*, and samples.

automobiles (Wood and Herlands 1993; Orenstein 2001), predation (Feinberg and Burke 2003), and heavy metals (Burger 2002) have decimated various Diamondback Terrapin populations. Their future in some regions may be in jeopardy.

A thorough knowledge of the biology of a species is necessary if conservation efforts are to be successful. An important part of this knowledge is determining rates of parasitism. In one study to assess the health of captive raised and wild Diamondback Terrapins, parasitism was not obvious in over 300 individuals (Werner et al. 2002). An extensive review of the literature on parasitism in the Diamondback Terrapin uncovered only four species of endoparasites, the latest published in 1960 (Werner 2003). The parasites identified were: a monogene, *Neopolystoma orbiculare* (MacCallum 1918); two trematodes, *Telorchis corti* (Wharton 1940) and *Pleurogonius malaclemys* (Hunter 1961); and a nematode, *Camallanus microcephalus* (Leidy 1888). Ectoparasites, such as barnacles (*Balanus ebumeus, Balanus improvisus, Chelonibia manati, and Chelonibia testudinaria*) and oysters (*Crassostrea virginica*) have been reported but their status as true parasites remains controversial (Werner 2003). As a result of these findings, the present study was conducted to further elucidate the parasitic status of the Diamondback Terrapin.

Materials and Methods

From May 2002 to August 2002, Diamondback Terrapins were examined for evidence of parasites from the following areas: Beaufort, North Carolina; Big Sable Creek, Florida; Stone Harbor, New Jersey; Wellfleet (Cape Cod), Massachusetts. In addition, in January 2003, a single Diamondback Terrapin from Lois Key, Florida was examined. The methods utilized were:

Physical examination.—Each turtle was visually inspected for the presence of any external parasites. Oral cavities were examined for polystomes (such as those described by Leidy in his 1888 paper) with a speculum and binocular loupe or an otoscope. Cotton-tipped applicators were then used to swab the oral cavities. Swabs were placed in containers of Ringer's solution and later examined with a dissecting microscope at 15–20x.

Fecal examination.—A zinc sulfate solution (specific gravity 1.020) was used as a flotation medium. Fecal samples were suspended in this solution and centrifuged at 1000 RPM for 10 minutes. A drop of fluid from the surface was examined microscopically at 100x for a minimum of two minutes for protozoa and ova from trematodes, nematodes, and acanthocephalins.

Cloacal flush.—Cloacae were irrigated with 1.0 ml of Ringer's solution. The aspirate was centrifuged at 1000 RPM for 10 minutes. The sediment was drawn into a pipette, placed on a microscope slide, stained with a drop of Lugol's stain and examined at 100x (similar to the fecal examination).

Blood.—Blood was collected from the dorsal coccygeal vein and two blood smears were made immediately. Later, smears were stained with a commercial thiazine and eosin preparation and examined at 400x. At least 10 fields containing a minimum of 10 cells were searched on one of the two slides for hemogregarines or microfilaria.

Necropsy.—A thorough necropsy of all tissues was done on two turtles injured by vehicles. The two individuals were euthanized with an intraperitoneal injection of Beuthanasia-D, a pentobarbital sodium solution (Schering-Plough, Kenilworth, New Jersey). Since populations may be on the decline in many areas, it was deemed unjustifiable to sacrifice any healthy individuals for necropsy. Tissues were examined grossly, then with a dissecting microscope. The liver, lungs, and kidneys were macerated in a saline solution for examination while the digestive tract was sectioned, opened, and flushed. Both the lining and the flushed material were checked stereoscopically. The trachea and bladder were examined using a "squash" preparation between two microscope slides. The heart was flushed with saline and the resulting fluid was examined stereoscopically.

Results

Physical examinations were performed on 83 Diamondback Terrapins (Table 1). There was no evidence of parasites in any of the 83 oral cavities. The only sign of possible external parasitism was the observation of some small oyster shells (genus and spe-

cies not determined) on the carapace of one Cape Cod turtle. Blood smears collected from 74 terrapins were all negative for intracellular parasites and microfilaria (Table 1). None of 59 cloacal flushes were positive for parasitic ova. Four of the 27 fecal flotations were positive for parasitic ova but only one egg was found in each of the four positive samples. The eggs were tentatively identified by Thomas Nolan (School of Veterinary Medicine, University of Pennsylvania) as typical for an ascarid or a trematode. Two of the samples were from Stone Harbor, NJ, one was from Beaufort, NC, and one was from Big Sable Creek, FL. Several samples contained centric diatoms, which might be confused with parasite eggs.

The two necropsies did not reveal any parasites in the oral cavity, respiratory tract, heart, liver, gastrointestinal tract, or urinary tract.

Discussion

If the results of this study are combined with those of Werner (2002), it would appear that parasitism is rare or non-existent in the Diamondback Terrapin. No hemoparasites or filaria were identified in any of the blood smears from either study. Fecal samples and cloacal flushes from the present study yielded only a few possible parasitic ova. There was never more than one egg found in any of the positive samples. One would expect to find several eggs in a fecal sample from a parasitized animal. Because the Diamondback Terrapin is known to be a non-selective carnivore with a diet that can include crabs, periwinkles, mussels, snails, annelids, fish, and carrion (Ernst et al. 1994) it is possible that the few ova seen may have come from the terrapin's food sources rather than from the terrapin. The results for all of the geographic areas sampled were almost identical. Even though the sample sizes from any one area were not very large, it seems unlikely that every tested terrapin would be negative for parasites unless parasites were uncommon. Some authors suggest that virtually all wild reptiles have parasites (Lane and Mader 1996).

As with any negative data on rates of parasitism, there are a number of methodological reasons why parasites might have been missed, including: (1) parasites present but not shedding ova; (2) insufficient necropsies; and (3) sample collection at the wrong time of year. In addition, there are several biological reasons why *M. terrapin* may actually be parasite free, including: (4) natural resistance of the host; (5) lack of intermediate hosts to complete parasite life cycles; (6) ingestion of natural vermifuges. Further examination of other populations may eventually uncover parasites for *Malaclemys terrapin* but at the present time this turtle seems to be practically devoid of parasites.

Condition and Immune Traits of Frogs from Ontario Baitshops: Risks of Practice not Ameliorated by Sale of Healthy Frogs

PAMELA L. RUTHERFORD*

A common practice in some of the Canadian provinces and many US states is the sale of live frogs and fish such as minnows, as well as leeches, earthworms and other organisms, for the recreational fishing industry. One such industry, the frog baitshop industry in Ontario, has recently come under scrutiny (Brousseau et al. 2003). Two main perceived risks of this industry include local overharvesting of frogs, and potential transmission of parasitic or pathogenic organisms to other populations (Brousseau et al. 2003). Given these risks, it is paramount to ensure both that benefits of the industry are large and that measures have ensured the sale of healthy frogs.

In this paper, our main objective is to determine whether Ontario baitshops are involved in the sale of healthy frogs, given the risks of this industry and small revenue generated. While the revenue generated by Ontario baitshops is estimated at $40–60 M yearly

by the Ontario Ministry of Natural Resources (OMNR), revenue from the sale of frogs is small: ca. $46,000 in 2002 (Brousseau et al. 2003). The main problem with stressful transport and housing of frogs is that this practice can result in die-offs of frogs in baitshops, making the net profit of the industry even smaller or putting further pressure on harvesting. Unhealthy frogs may also transmit bacterial infections to end users, and even results in the potential spread of disease to wild populations (a risk we entertain but do not address explicitly in this paper).

The risks perceived for the Ontario baitshop industry may be real. Commercial harvest has led to local population declines for other frog species elsewhere (reviewed by Blaustein et al. 1994). In 2001, the OMNR restricted capture and sale to only northern leopard frogs (*Rana pipiens*). There are, however, concerns about harvest of *R. pipiens*. This species is endangered in British Columbia, of special concern in the Prairie Provinces (Seburn and Seburn 1998) and potentially declining in southwestern Ontario (Hecnar 1997), and northern Ontario (Seburn and Seburn 2002). New regulations restrict the commercial harvest of frogs to eastern Ontario (Brousseau et al. 2003). Licensed dealers living outside the approved area can sell frogs, but the frogs must be harvested from inside the approved area. Abundance of *R. pipiens* at monitoring sites has suggested to some that the current restricted area can sustain a viable commercial *R. pipiens* harvest, whereas a region west of the harvest area cannot (Brousseau et al. 2003). Such population surveys may be of limited utility given that there is little information about normal population fluctuations for this species and other amphibians show marked short-term population fluctuations (Pechmann et al. 1991). There is also a question about the accuracy of records, e.g., annual returns from 2002 indicate that 27,000 more frogs were sold than were harvested (Brousseau et al. 2003). Such errors in assessing harvests can have strong implications for monitoring the impact of harvests on populations.

The risk of spread of parasites and pathogens from domestic or farmed animals back to natural populations of conspecifics or heterospecifics has been increasingly documented over the past decade (reviewed by Frölich et al. 2002; Mazzoni et al. 2003). Additionally, there has been a fear that such transmission back to the wild can occur from other practices. For example, increased susceptibility resulting from inbreeding, nutritional status, stress, or immunosuppression (all of which are often associated with high-density situations) may increase the efficiency of transmission to new hosts (Scott 1988). Thus, the risk of disease spread from baitshops may also be real, especially given the recent studies indicating ranaviral diseases in local areas in Ontario and current regulations about harvest areas, which encourage translocation of frogs (Brousseau et al. 2003).

Our main objective was to compare indices of health of juvenile *R. pipiens* captured and sold in baitshops to local frogs of the same age and size. If baitshops are typically not engaged in the sale of healthy frogs then revenues may not be increased much above current levels and may even be substantially reduced in some seasons due to die-offs in baitshops. Importantly, the loss of unhealthy frogs also could place more pressure on continued harvesting. It is likely that die-offs in baitshops, which have been observed (M.R. Forbes, pers. observ.), are episodic and thus not reported consistently. Further, frogs may be sold before they show outright symptoms of disease but can be assessed for general health (before being sold) using other metrics. As such, we were not addressing potential for disease spread to wild populations (although we believe this to be a risk) because such assessments would require more sophisticated approaches. Rather, we measured body mass, snout-to-vent lengths, leukocyte differentials (lymphocyte and neutrophile) and organ mass (spleen and liver) of juvenile *R. pipiens* as interrelated indices for assessing frog health.

We evaluated nutritional status using both body mass and liver mass, relative to body size. One of the primary roles of the liver is to store and process fats and proteins (Martini 1998). Individuals that are stressed, in ill health, or responding to an infectious disease also may have elevated leukocyte numbers (Bubenik and Brownlee 1987). Thus, we assessed amphibian leukocytes which consist mainly of neutrophils and lymphocytes, with eosinophils, basophils, and monocytes comprising the remainder of leukocyte cells. Neutrophils are phagocytic and mainly function in innate immune response, whereas lymphocytes function exclusively in acquired immune responses (Horton and Ratcliffe 1998). In most cases the increase in leukocyte numbers is caused by a rising number of neutrophils and lymphocytes in the peripheral blood (Rose et al. 1979). Conversely, individuals with lower lymphocyte numbers can be more susceptible to viral infections (Fitzgerald 1988; Siegel 1985). Examination of the spleen will help elucidate the frog's immune status. In amphibians, the spleen is a major peripheral lymphoid organ (Horton and Ratcliffe 1998), and splenomegaly has been shown in response to a naturally occurring infection in a frog species (Haynes et al. 1992).

Materials and Methods.—Eleven baitshops were chosen based on their close proximity to the Queens University Biological Station, Ontario, Canada (QUBS; 4534'N, 7613'W) where the wild-caught frogs were captured. Collection dates ranged between 30 July and 16 August 2000. In each baitshop, six juvenile frogs were selected by the baitshop owners for a total of 66 frogs from the 11 baitshops. Frogs were placed in a plastic bait bucket and then brought immediately back to QUBS. The maximum time any frog spent in transit was two hours, including frogs collected directly from the wild. Juvenile wild-caught frogs were collected in two fields that were situated next to ponds approximately ten kilometers west of QUBS. Collections were timed with baitshop visits to control for possible seasonal effects (two collection dates: 22 July and 13 August 2000).

Blood smears were made for baitshop and wild-caught frogs. In this procedure, 0.03 mL of blood was aseptically extracted via cardiac puncture, and spread on a new microscope slide using another new slide. The blood smear was air dried and placed into a slide storage container. Blood slides were sent to Vita-tech (Veterinary Laboratory Services in Markham, Ontario, Canada) for differential leukocyte analysis. For standard differential counts, 100 leukocytes were evaluated per smear and classified as neutrophils, lymphocytes, eosinophils, basophils, and monocytes. We excluded counts of eosinophils, basophils, and monocytes because counts of these cell types have been shown to have low repeatability (e.g., Pap 2002).

After withdrawing blood, frogs were placed separately in plastic containers and set in an ice bath for approximately one hour (or until their body temperature was lowered to). Frogs were removed from the ice bath, measured for snout-vent length (SVL), and double pithed. Each frog was dissected to determine its sex and its

liver, and spleen was removed. Wet mass for each organ was assessed with a Mettler AE 100 electronic balance scale accurate to 0.1 mg. Sex was determined by dissection.

Frogs with significantly higher SVL, microfilarial and protozoan parasites, and poor quality blood smears were excluded from subsequent analyses. The final dataset used in all analyses included 36 juvenile baitshop frogs (14 males and 22 females), and 36 juvenile wild-caught frogs (26 males and 10 females). All statistical analyses were performed using R (Ihaka and Gentleman 1996). Morphometric variables were natural-log transformed to meet the assumption of normality, and significance was assessed at P equals 0.05.

Results.—We did an analysis of co-variance (ANCOVA) to detect whether the relationships between SVL and body mass co-varied with treatment or sex nested within treatment. The interactions between SVL and treatment, and SVL and sex (nested within treatment) were non-significant and were dropped from the model. Body mass increased with SVL ($F = 739.82$, $P < 0.001$; Fig. 1A). Wild-caught frogs were heavier for their SVL than baitshop frogs ($F = 15.37$, $P < 0.001$; Fig. 1A). There was no significant difference between juvenile males and juvenile females in body mass ($F = 0.11$, $P = 0.89$).

We did an ANCOVA to detect whether the relationships between SVL and organ masses co-varied with treatment or sex (nested within treatment). Separate ANCOVAs were used for the spleen and liver. The interactions between SVL and treatment, and SVL and sex (nested within treatment), did not explain significant variation in organ masses. Both interaction terms were dropped from the models. Organ mass increased with SVL for the spleen ($F = 16.39$, $P < 0.001$; Fig. 1B), and liver ($F = 134.84$, $P < 0.001$; Fig. 1C).

Spleens from baitshop frogs were significantly larger than spleens from wild-caught frogs ($F = 6.09$, $P = 0.016$; Fig. 1B). In contrast, livers were significantly smaller in baitshop frogs compared to wild-caught frogs ($F = 18.53$, $P < 0.001$; Fig. 1C). There were no significant differences between juvenile males and juvenile females in mass of either of the organs (spleen: $F = 0.43$, $P = 0.65$; liver: $F = 0.062$, $P = 0.94$).

We tested whether the proportion of leukocytes that were lymphocytes or neutrophils was related to SVL, treatment, or sex (nested within treatment) using a logistic regression. We used quasibinomial errors because the data were overdispersed (McCullagh and Nelder 1989). Significance of the terms in the model was assessed with an F-test. Wild-caught frogs had a higher proportion of lymphocytes ($F = 11.52$, $P = 0.001$; Fig. 2). There was no relationship between SVL and lymphocyte proportion ($F = 0.13$, $P = 0.72$), and there was no difference between the sexes ($F = 1.18$, $P = 0.31$). Baitshop frogs had higher proportion of neutrophils ($F = 4.82$, $P = 0.03$; Fig. 2). There was no relationship between SVL and neutrophile proportion ($F = 0.32$, $P = 0.57$), and there was no difference between the sexes ($F = 0.81$, $P = 0.45$).

Discussion.—Our results suggest that juvenile baitshop *R. pipiens* frogs are not as healthy as juvenile wild-caught frogs. Baitshop frogs weighed less, and had lighter livers as compared to wild-caught frogs after correcting for body size. One of the primary roles of the liver is to store and process fats and proteins (Martini 1998). Because frogs are not fed in baitshops and can be housed for long periods (McRuer 2001), the natural metabolism

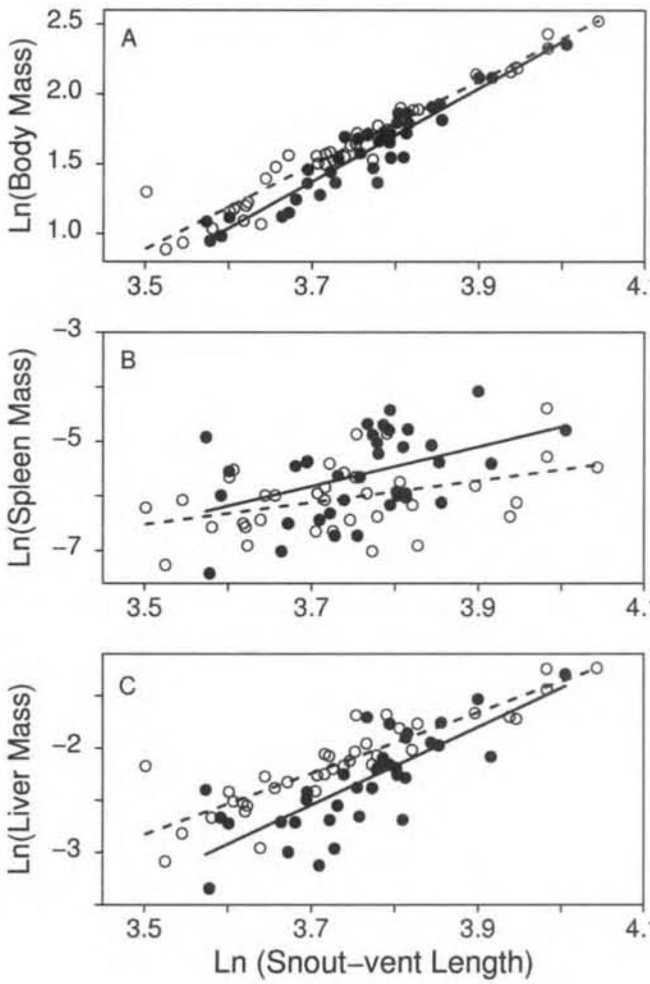

FIG. 1. Snout–vent length (mm) versus A) body mass (g), B) spleen mass (g), and C) liver mass (g) of juvenile *Rana pipiens* as found in baitshop (closed circles and solid line) versus wild-caught frogs (open circles and dashed line). All variables are natural-log transformed.

of the liver's stores of fat may account for its weight loss in baitshop frogs. Therefore, the relatively smaller livers and reduced body mass may be an indication of poor nutritional status in the baitshop frogs compared to their wild-caught counterparts.

In addition, relative spleen mass and leukocyte profiles were clearly different between the two groups of frogs. Baitshop frogs had heavier spleens (relative to body size) than wild-caught frogs. Splenomegaly has been shown in response to a naturally occurring infection in a frog species (Haynes et al. 1992). Baitshop frogs had a lower proportion of lymphocytes and a higher proportion of neutrophils compared to wild-caught frogs. The elevated neutrophil levels and diminished lymphocyte levels in the baitshop frogs are indicative of animals that are stressed, in ill health, or responding to an infectious disease (Bubenik and Brownlee 1987; Rose et al. 1979). For example, this same response has been shown in the newt *Notophthalmus viridscens* in response to a variety of stressors: hydrocortisone injection (Bennett et al. 1972), corticotrophin injection and osmotic stress (Bennett and Johnson 1973), continuous light (Bennett and Reap 1978), and constant high or low temperatures (Bennett and Daigle 1983).

The magnitude of the blood cell component changes we saw

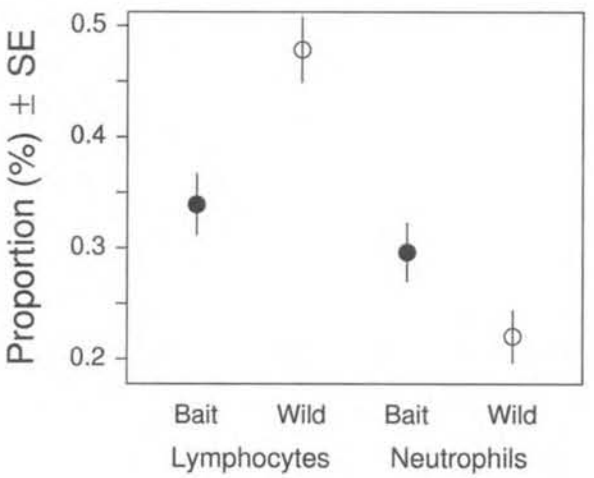

FIG. 2. Mean proportion (± SE) of leukocytes that are lymphocytes and neutrophils in juvenile *Rana pipiens* as found in baitshop (black) and wild-caught frogs (white). Proportions and SE are predicted values from a logistic regression with quasibinomial errors.

were consistent with amphibians given hydrocortisone injections (Bennett et al. 1972). The long-term consequences on the condition and viability of amphibians to changes of this magnitude are not known. Also, it is not known how long it would take to restore liver and spleen masses, and blood components back to 'normal' levels.

There are two main implications of baitshops housing and selling unhealthy frogs: local overharvesting of frogs, and potential transmission of parasitic or pathogenic organisms to other populations. Our data cannot identify if overharvesting of *R. pipiens* is occurring. Nonetheless, unhealthy baitshop frogs are likely to increase the number of episodic die-offs, which may lead to additional frog harvesting to replace these animals. Detailed data on the frequency of these die-offs and the number of 'replacement' frogs harvested would be required to identify if this is a real concern.

Our results also provide preliminary information about the potential for disease spread among baitshop frogs and from baitshop frogs to natural populations of conspecifics or heterospecifics. Baitshop frogs have lower lymphocyte proportions making them more susceptible to viral infections (Fitzgerald 1988; Siegel 1985). In addition, baitshop frogs have reduced nutritional status. A number of studies have shown that prolonged nutrient limitation can reduce immunocompetence (Apanius 1998). Our data do not identify the frequency and severity of disease transmission directly resulting from the use of frogs in the baitshop industry. We are able to show that baitshop frogs are not healthy and the risk of disease transmission is a valid concern that needs to be addressed. This is especially important given that current regulations encourage translocation of frogs (Brousseau et al. 2003).

It is evident that further research is needed to identify whether this (or any other) frog baitshop industry is sustainable. Certainly the risks need to be balanced against the benefits. Current data indicates that the frog baitshop industry in Ontario is not thriving and is engaged in the sale of unhealthy frogs. This increases the risk of die-offs and loss of profit to baitshop owners, and likely does not ameliorate the risk of disease transfers.

Acknowledgments.—We thank the staff at the Queens Biology Station (F. Phelan and F. Connor) for logistical support. Field assistance was provided by K. Kissner, C. Turnbull, J. McRuer, M. Lajeunesse, K. Cavy, S. Hawco, G. Glen-Whorral, A. Soutar, A. Stevens, G. and C. Blouin-Demers, and R. Grant. Lab assistance was provided by C. Wyndham and G. Kit. The increased availability of air transport around the world has greatly expanded the variety and numbers of wild species traded for use as pets (Roe et al. 2002). The European Union represents, along with the United States, one of the largest markets for the international pet trade. Reptiles especially have become very popular and wild populations have to sustain important off-takes to supply this market. According to Lawson (2002), nearly 210,000 live CITES-listed reptiles (excluding crocodilians and turtles/tortoises) and amphibians were legally imported into the EU in 1999, 30% of which were taken from the wild.

France is an important market for exotic reptile pets in Europe. For lizards and snakes (Squamata), the major European importers are Spain, Germany, the Netherlands, UK, Belgium, and France, respectively (Auliya and Berkhoudt, in prep.). The diversification in professional distribution channels for exotic pets in France (garden centers, do-it-yourself stores, franchise pet shops, agricultural self-service shops, etc.) illustrates the booming of this market and shows the confidence of French investors in this trade. Furthermore, it appears that local, regional and national commercial pet exhibitions have a great success and attract more and more people.

Recognizing the growing popularity of reptiles as pets in France, and the lack of data relative to French imports, TRAFFIC Europe-France sought to examine the imports in live CITES-listed reptiles —volumes, variety, dynamics, trends, and origins over a 10-year period, 1990–1999. This paper presents the main results for lizards.

Material and methods.—The main sources of data for the international wildlife trade estimations are the annual reports compiled by the Parties to the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). The data source consulted for this study was the annual CITES reports that are held in databases by the United Nations Environment Programme – World Conservation Monitoring Centre (UNEP – WCMC). The trade data presented in this study represent a compilation and analysis of the comparative tabulation UNEP-WCMC database. The analysis provides a detailed look at the data, and enables the comparison of reported exports with reported imports, by species, item (i.e., number of live animals), country of export/import, reported sources (e.g., wild, captive-bred, artificially propagated, etc.) and by purpose of trade (e.g., commercial, scientific, personal, etc.) (UNEP - WCMC 2003).

Often there are discrepancies between export and import figures in the comparative tabulation. On many occasions this was due to the item, the source, and/or the purpose of trade being reported differently by the importing and exporting countries.

- Item: if trade was reported differently by the importer and exporter the report used whichever figure was the greater, and if trade was reported only by one country the report kept the information to avoid underestimating the trade.
- Source and purpose: if trade was reported differently by the importer and by the exporter, the report used the exporter data, only using importer data if exporter data were unavailable.

Despite these limitations, these data still present a valuable and important source of information and provide a good indication on general trends in the trade.

Figures in this paper included just a part of the trade with the French dependent territories to which the Convention applies. This is because France usually does not specifically mention the name of its overseas departments, overseas territories, territorial communities or various islands in its annual reports (all transactions with dependent territories are usually mentioned as taking place with France instead of with French Guyana, Guadeloupe, Martinique, etc.). However, some information on trade in CITES-listed animals with French dependent territories is stored in the UNEP-WCMC CITES database, emanating only from the annual reports of the countries that were partners in the transactions. Furthermore, transactions with New Caledonia are specified as such since New Caledonia produces its own annual report independently from the annual report for France. These pieces of information with the French dependent territories are excluded from the analysis.

Overview of CITES-listed reptile trade.—According to the reported CITES trade data, 197,983 (96%) of the 206,563 live reptiles traded by France between 1990 and 1999 were imports. Furthermore, 90% of CITES-listed reptiles were imported into France for commercial purposes. Therefore, France can really be

considered as a consumer country of live CITES-listed reptiles, supplying a pet market.

Figure 1 shows that during the first half of the nineties, the number of CITES-listed reptiles imported was nearly constant (11,209 ± 1,925 specimens), whereas it shows a regular and drastic increase from 1994 to 1999 (+ 273%). The majority of imports concerned lizards (52%), which accounted for most of the increase in the total number of live reptiles, then snakes (27%), turtles and tortoises (20%), and crocodilians (1%).

Species of particular concern.– Iguanas, chameleons, geckos, agamids, and varanids were by far the most important CITES-listed lizard families imported and traded in French pet shops in the nineties, accounting for almost 99% of all recorded CITES-listed lizard trade from 1990 to 1999 (Table 1). The top five CITES-listed lizard species imported over this period were Green Iguana *Iguana iguana* (42,683 specimens, i.e. 41.1% of the total number of lizards imported between 1990 and 1999), Madagascar Day Gecko *Phelsuma madagascariensis* (5,921 specimens, 5.7%), Bell's Dabb Lizard *Uromastyx acanthinura* (5,202 specimens, 5.0%), Senegal Chameleon *Chamaeleo senegalensis* (5,123 specimens, 4.9%), and African Savanna Monitor *Varanus exanthematicus* (3,915 specimens, 3.7%).

Trends during the 1990s.– Evolution of imports: Table 2 shows the evolution of imports for the main CITES-listed lizard families in trade. The total number of specimens imported during the first half (1990–94) of the nineties was nearly constant (5,061 ± 860 specimens), whereas it shows a regular and drastic increase from 1994 to 1999 (+ 253%). Green iguanas accounted for a significant part of the increase in the total number of live lizards imported in the second half of the 1990s (apart from the decrease in 1996). Imports of chameleons, geckos, agamids and varanids also accounted for this increase but to a smaller extent.

Characteristics of the French market.– Figure 2 shows that the number of CITES-listed lizard species imported per year into France was quite stable (37,8 ± 4,6) and the number of new species appearing in trade was regular (5,1 ± 2,1). Furthermore, during the nineties, 62% of species were imported over a five year period or less, whereas only 16% were imported during a period of seven years or more. There are therefore some species that are imported on a regular basis to meet constant demand (e.g. *Iguana iguana, Phelsuma madagascariensis, Chamaeleo senegalensis, Varanus exanthematicus*), whilst other species are only in demand during a limited time period and appear only sporadically in the data depending on changing trends in purchaser demand (e.g., *Chamaeleo eisentrauti, Phelsuma cepediana, Phelsuma dubia, Bradypodion fischeri*).

Origin of CITES-listed lizard species imported into France.– This trade targets only a few countries. A total of 40 countries have exported live CITES-listed lizards to France in the nineties, but twelve of them supplied nearly 90% of this trade. Figure 3 shows the main routes for this trade, according to the families concerned.

Green iguanas.– France has imported approximately 80% of specimens from the United States, 15% from Colombia and the remainder from Central and South American countries, appearing in the second half of the nineties: Nicaragua, Costa Rica, Bolivia and Chile. However, the United States is exclusively a re-exporting country because their specimens came from Colombia (52%), El Salvador (38%) or Suriname (10%). The vast majority of live CITES-listed Green iguanas imported for the French pet market were bred in captivity (86%), whilst other specimens were taken from the wild. For example 1,300 and 2,100 wild specimens were imported from Suriname respectively in 1998 and 1999.

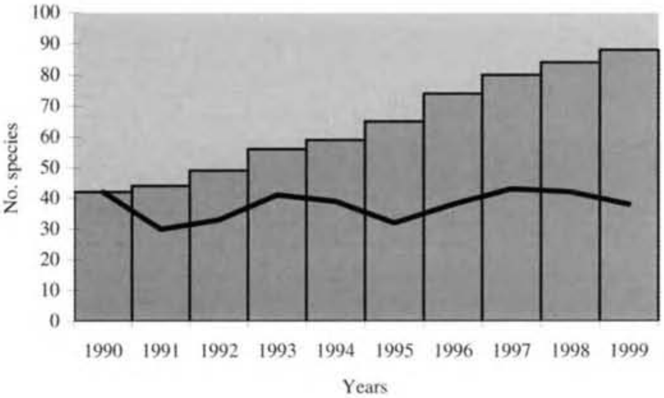

Fig. 2. Number of CITES-listed lizard species imported into France per year (line) and cumulative number of species imported (bars). Source: TRAFFIC analysis of UNEP-WCMC data, 2002.

Chameleons.– The status of chameleons within CITES has changed with the 12th meeting (Chile, 3–15 November 2002) of the Conference of the Parties to CITES. Indeed, all *Brookesia* species were included in Appendix II, except for *B. perarmata*, which was included in Appendix I (amendments to Appendices I and II of the Convention entered into force on 13 February 2003). The analysis for the present study covers the years 1990-1999, and therefore does not take *Brookesia* species into account. However, according to the Species Survival Network (2002), these species are in international trade, as Madagascar exported nearly 2,300 *Brookesia* specimens (excluding *B. perarmata*) in 2000 and 2001, mainly destined for pet markets in the United States and Europe. CITES-listed chameleons are principally imported from Madagascar (37%), Togo (20%), Burundi (14%), Tanzania (8%) and Benin (6%). Imports from Madagascar involved only specimens taken from the wild and concerned both the genera *Calumma* and *Furcifer*. *Calumma* exports from Madagascar stopped in 1995, whereas *Furcifer* exports (principally Carpet Chameleon *Furcifer lateralis* and Panther Chameleon *Furcifer pardalis*) increased in the second half of the nineties. Togo exported only two species: Senegal Chameleon *Chamaeleo senegalensis* (3,975 specimens) and Graceful Chameleon *Chamaeleo gracilis* (725). Specimens of Senegal Chameleon were exclusively taken from the wild and exports show an increase in exports during the second half of the nineties. Import of Graceful Chameleon began in 1996 and increased until 1999, with nearly 60% of specimens taken from the wild and 40% coming from ranching operations. In Togo, four farms raise reptiles for the export trade and are located in Lome (Toganim, Pajar, Fexas, and Mare). They share approximately 95% of the export quota between them while the other eight registered establishments share the remaining 5% of the quota (Harris 2002). Eighty percent of Burundi's exports (1990–1999) were realized in 1990, 1991, and 1992 and concerned only wild chameleons. From 1993 to 1999, Tanzania exported nine different species, exclusively taken from the wild, of which seven were from the genus *Chamaeleo* (*C. bitaeniatus, C. dilepis, C. fuelleborni, C. gracilis, C. jacksoni, C. melleri,* and *C. rudis*) and two from the genus *Bradypodion* (*B. fischeri* and *B. tavetanum*). Chameleon imports from Benin involved exclusively two species—Graceful Chameleon and Senegal Chameleon. From 1993 to 1995 Senegal Chameleons imported from Benin were taken from the wild, but since 1996 they have been derived from ranching operations. Graceful Chameleon imports began in 1996 and involved exclusively specimens from ranching operations.

Geckos.—During the 1990s, CITES-listed geckos were exclusively imported from Madagascar and taken from the wild. Figure 4 shows that in the first half of the nineties, France imported 15 gecko species whereas in the second half, imports focused on four species with a significant increase in their imports: the Gold-dust Day Gecko *Phelsuma laticauda* (+ 95%), the Madagascar Day Gecko *P. madagascariensis* (+ 82%), the Peacock Day Gecko *P. quadriocellata* (+ 83%), and the Lined Day Gecko *P. lineata* (+ 74%).

Agamids.—Ninety per cent of the CITES-listed agamids (*Uromastyx* spp.) were imported from Mali and involved only two species taken from the wild: Bell's Dabb Lizard *U. acanthinura* and *U. dispar*. Imports began in 1995 (1,000 specimens), increased in 1996 (4,866) then decreased until 1999 (no imports). Other agamids (10%) were occasionally imported from Egypt and Sudan: the Egyptian Dabb Lizard *U. aegyptia* and the Eyed Dabb Lizard

U. ocellata.

Varanids.—Although 14 countries supplied the trade in varanids between 1990 and 1999, the majority of varanids were imported from Togo (47%), Ghana (16%), Benin (13%) and Indonesia (13%). Togo, Ghana, and Benin have exported both species present in their country: the Savannah Monitor *Varanus exanthematicus* and the Nile Monitor *V. niloticus* [note that *V. niloticus* is in fact composed of two species, one restricted to open savannas, the true *V. niloticus*, and another restricted to more closed forested areas, *V. ornatus* (Böhme and Ziegler 1997); both species are generally referred to as *V. niloticus* in CITES permits]. Table 3 shows that total imports of Savannah Monitor and Nile Monitor from these countries decreased between 1990 and 1992 then increased regularly until 1998/99. Imports from Togo, the main supplier, showed a sharp increase in the second half of the nineties, whereas imports from Ghana were more uneven (only six years of imports during the nineties) and imports from Benin showed a significant decrease in 1998 and 1999. From 1990 to 1994, specimens of both taxa were exclusively taken from the wild in those countries but since 1995 Togo and Benin have developed ranching operations. Therefore, since 1995, 41% and 88% of specimens imported from Togo and Benin respectively, issued from ranching operations. Varanid specimens imported from Indonesia were nearly four times more numerous from 1995 to 1999 (1,007 specimens) than from 1990 to 1994 (249). There are two reasons for this increase: five species (*V. dumerilii*, *V. indicus*, *V. rudicollis*, *V. salvadorii*, and *V. salvator*) which were occasionally imported from 1990 to 1994, were imported regularly and in larger numbers from 1995 to 1999. Furthermore, six additional Australasian species appeared in trade between 1995 and 1999 (*V. bogerti, doreanus, jobiensis, panoptes, prasinus,* and *timorensis*).

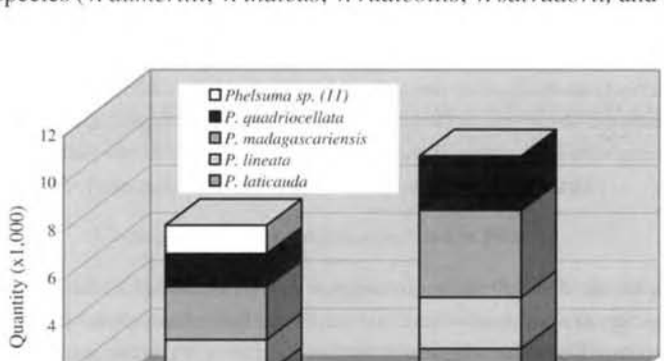

FIG. 4. Number and composition of CITES-listed geckos imported from Madagascar to France (1990–1999). Source: TRAFFIC analysis of UNEP-WCMC data, 2002.

Conclusions and discussion.—Hoover (1998) has shown that the international trade in live reptiles has grown dramatically in the last decade. Our data show that France followed this trend, but with a time delay, as French imports have only grown dramatically in the second half of the nineties. Our focus in the French trade CITES-listed lizards shows that:

Green iguanas, chameleons, geckos, agamids, and varanids were by far the most important CITES-listed lizard families imported and traded in French pet shops in the nineties, accounting for almost 99% of all recorded CITES-listed lizard trade between 1990 and 1999.

Green Iguanas *Iguana iguana* made up more than 40% of total French imports of CITES-listed lizards in the nineties. However, there are other species found in trade in substantial numbers, including Madagascar Day Gecko (*Phelsuma madagascariensis*), Bell's Dabb Lizard (*Uromastyx acanthinura*), Senegal Chameleon (*Chamaeleo senegalensis*), and African Savanna Monitor (*Varanus exanthematicus*).

Imports of iguanas first, then imports of chameleons, geckos, agamids, and varanids accounted for the dramatic increase in the total number of lizards imported between 1994 and 1999. Some species were imported on a regular basis to meet a constant demand (see previous section), while other species were in demand for a limited period and appeared only sporadically in the data depending on changing trends in purchaser demand (e.g., *Chamaeleo eisentrauti, Phelsuma cepediana, Phelsuma dubia, Bradypodion fischeri*).

West Africa, Madagascar, Central, and South America were the main regions supplying the CITES-listed lizard trade in France. Agamids, varanids, and a fraction of the chameleons were principally imported from West African French-speaking countries (Togo, Benin, Mali) and from Ghana, a West African English-speaking country. Another part of the chameleons (genera *Calumma* and *Furcifer*) and all CITES-geckos were imported from Madagascar. Iguanas originated from Central and South America (Colombia, Nicaragua, El Salvador), even if the United States played a significant role as a re-exporter. A reason why the United States plays a significant role in this trade is because of its relationship. For example, the single largest iguana producer in El

TABLE 3. The most important suppliers of the two main varanid species imported into France (1990-1999). *Source:* TRAFFIC analysis of UNEP-WCMC data, 2002.

Salvador (and probably in the world) is an American-owned and operated business. The owner sends most of his iguanas to the United States, at least in part because he has a similar business in the U.S. and because he has long-standing relationships with several other reptile dealers in the United States (Hoover, pers. comm. 2002).

This paper shows that, since 1995, most CITES-listed lizards imported into France were bred in captivity or issued from so-called "ranching operations." The main reason is that the great majority of Green Iguanas (which account for nearly 40% of the total CITES-listed lizard imports to France) were bred in captivity. Captive breeding and ranching of reptiles may reduce overexploitation of some species in the wild. However, many of the captive breeding, farming and ranching operations that supply the global reptile market need wild-harvested animals to maintain their breeding stocks. Furthermore, the percentage of specimens taken from the wild is significantly higher for other groups of lizards imported for the French pet market: agamids (100%), geckos (91%), chameleons (77%), and varanids (64%).

Therefore, with the growing demand for CITES-listed live lizards as pets and the significant proportion of wild-caught specimens, it seems necessary to increase the monitoring of international trade and to encourage taxonomic studies. According to a Nomenclature Committee report prepared for the twelfth meeting of the Conference of the Parties, no standard references have been adopted yet for the frequently traded lizards of the genera *Phelsuma* and *Uromastyx* and several new species have recently been described in both genera. Therefore, the Nomenclature Committee proposed a budget of USD 18,000 for the period Cop12 and Cop13 to cover expenditures related to its activities concerning the nomenclature of the genera *Phelsuma* and *Uromastyx*.

Our data only concern CITES-listed lizards, but most of the imported lizard species are not listed on CITES appendices. Our lack of data concerning those species is a great problem because most of them are taken in the wild and we have no idea of pressure levels on their populations. There is (we hope only for the moment) no way to obtain such data! Some species of particular concern include several geckos (*Geckonia chazaliae*, *Hemitheconyx caudicinctus*, *Teratolepis* spp.), agamids (*Acanthosaura* spp., *Leiolepis* spp., *Physignathus* spp.), and iguanids (*Basiliscus* spp.).

Acknowledgments.—This study was supported financially by WWF-France. We thank UNEP-WCMC for providing comparative tabulation CITES database. All colleagues at TRAFFIC, a programme of the WWF and The World Conservation Union (IUCN), who collaborated on this study are particularly thanked for their contribution.

March 2004 at 1120 h, another *T. strigatus* (MCNR 988, 219 mm SVL) was captured on the edge of the same stream within 60 cm of two calling male *Crossodactylus* cf. *bokermanni* (SVL 23.8 and 22.0 mm). *Thamnodynastes* are primarily nocturnal, as are the majority of anurans that comprise their diet (Bernarde et al., *op. cit.*; Marques et al. 2001. Serpentes da Mata Atlântica. Guia Ilustrado para a Serra do Mar, Ribeirão Preto. Holos. 184 pp; Rufatto et al., *op. cit*). This is the first record *T. strigatus* preying on a diurnal anuran.

Submitted by **KATIA KOPP** (e-mail: kakopp@hotmail.com) and **MILENA WACHLEVSKI** (e-mail: milenawm@yahoo.com), Laboratório de Ecologia Evolutiva de Anfíbios e Répteis, Programa de Pós Graduação em Zoologia de Vertebrados, Pontifícia Universidade Católica de Minas Gerais, 30535-610, Belo Horizonte, Minas Gerais, Brazil.

TRIMERESURUS ALBOLABRIS (White-lipped Pitviper). **RESTING SITE**. Although *Trimeresurus albolabris* is occasionally found hunting on the ground at night, most accounts report that it is predominantly arboreal (Cox 1991. The Snakes of Thailand and their Husbandry. Krieger Publishing Company, Malabar. 526 pp.; Cox et al. 1998. A Photographic Guide to Snakes and other Reptiles of Thailand and Southeast Asia. Asia Books, Bangkok. 144 pp.; Das 2002. A Photographic Guide to Snakes and other Reptiles of India. New Holland Publishers, London. 144 pp.). Our own encounters have been primarily with individuals in trees and bushes, although several individuals were encountered moving on the ground at night (CAS 210108, 210665, 210690, 210691). Cox et al. (*op. cit.*) mention that during the day *T. albolabris* is typically found at rest in vegetation. On 13 April 2002 at 1609 h, one of us (HW) unearthed a male *T. albolabris* (625 mm SVL, 85 g; CAS 224646) near Nagmung Town, Kachin State, Myanmar (27°30'36.5"N, 97°49'50.4"E, WGS 84) at 613 m elev. The snake was inactive ca. 25 cm below ground level inside a termite mound located near a trail in an agricultural area in the midst of subtropical evergreen forest. This is the first record of any *Trimeresurus* using a termite mound as a retreat. We thank U Khin Maung Zaw, Alan Leviton, Jens Vindum, and the National Science Foundation (DEB-9971861).

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother 2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. SSAR Herpetol. Circ. 29:1–82, available online at <http://herplit.com/SSAR/circulars/HC29/Crother.html>; for Mexico as it appears in Liner 1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*. Herpetol. Circ. 23:1–113), LOCALITY (use metric for distances and give precise locality data), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author—curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Leviton et al. 1985. *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology*, Copeia 1985[3]:802–832) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief), SUBMITTED BY (give name and address in full—spell out state or province names—no abbreviations).

Some further comments. This geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens which have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality color slide or photograph may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Color slides and photographs *must* be deposited in a university or museum collection along with complete locality data, and the color slide catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary) to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extensions unless a thorough literature review has been completed.

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **Alan M. Richmond** (USA & Canadian records only); **Jerry D. Johnson** (Mexico and Central America, including the Caribbean islands); **Hidetoshi Ota** (all Old World records); or **Gustavo J. Scrocchi** (South American records). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Schmitz, A., and T. Ziegler. 2003. Geographic distribution. *Sphenomorphus rufocaudatus*. Herpetol. Rev. 34:385.

CAUDATA

NOTOPHTHALMUS VIRIDESCENS LOUISIANENSIS (Central Newt). USA: INDIANA: Posey Co: Point Township: 14 km SSW Mount Vernon at Twin Swamps Nature Preserve. 16 June 2004. Zack Walker, Nathan Engbrecht, Andrew Berger, and Michael Lodato. University of Michigan Museum of Zoology (UMMZ 232002–06). Verified by Greg Schneider. New county record and first record for "pocket" of extreme SW Indiana. (Minton 2001. Amphibians and Reptiles of Indiana. 2nd ed., revised. Indiana Acad. Sci. 404 pp). Newts appear to be common at this locality with its bald cypress (*Taxodium distichum*) and overcup oak (*Quercus* lyrata) swamps surrounded by mature forest. Adults

were plentiful in aquatic situations while terrestrial juveniles were found in lesser numbers under cover. Its relative abundance at this site is in sharp contrast to the rest of SW Indiana where newts are generally unknown.

HYLA CHRYSOSCELIS (Cope's Gray Treefrog). USA: GEORGIA: EARLY Co: 85°0'43"W, 31°24'47"N. 17 June 2002. T. Muenz and L. Smith, Joseph W. Jones Ecological Research Center. GMNH 49908. Verified by J. Jensen. Individuals found within PVC pipe traps hung on trees at the edge of second-order streams. This locality represents a new county record (Williamson and Moulis 1994. Distribution of Amphibians and Reptiles in Georgia. Savannah Sci. Mus. Spec. Publ. No. 3, 712 pp.).

Submitted by **TARA K. MUENZ** and **LORA L. SMITH,** Joseph W. Jones Ecological Research Center, Newton, Georgia 39870, USA; e-mail: tmuenz@jonesctr.org.

HYLA EXIMIA (Mountain Treefrog). USA: NEW MEXICO: CIBOLA Co.: El Malpais National Monument: Temporary roadside pool along CR 42, ca. 2.7 rd. mi. S of SR 53, just E of the Continental Divide, UTM (NAD27) 12S, 763413 E, 3875108 N, ca. 2356 m. elev. 10 August 2003. A. J. Monatesti. MSB/USGS Biological Survey Collection, BS/FC 7818–20. Verified by Cindy Ramotnik. First record for Cibola County, and first verified record in New Mexico away from the Gila River basin. Extends range ca. 143 km NNE of closest records in the San Francisco Mountains region near Reserve, Catron County, New Mexico (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. University of New Mexico Press, Albuquerque, 431 pp.; Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, Third Edition. Houghton Mifflin Co., Boston, Massachuseets, 533 pp.). This record lends credence to 19th century specimens collected at Nutria,

McKinley County (Gehlbach 1965. Proc. U.S. Nat. Mus. 116 [3505]:243–332), the surviving specimen of which was poorly preserved and unidentifiable by Gehlbach (*op. cit.*). This new Cibola County locality is ca. 56 km SE of Nutria, and more or less contiguous upper elevation forested habitats associated with the Zuni Mountains connect them, suggesting the species may be more widespread in the region. However, this northern region is separated from populations to the south by large areas of lower elevation woodland, savanna, and grassland habitats (Dick-Peddie 1993. New Mexico Vegetation, Past Present, and Future. University of New Mexico Press, Albuquerque. 244 pp.).

Submitted by **A. J. MONATESTI** (e-mail: ajmonatesti@yahoo.com), **TREVOR B. PERSONS** (e-mail: Trevor.Persons@nau.edu), and **ERIKA M. HYLA ROSENBERGI (Rosenberg's Gladiator Treefrog). COLOMBIA: DEPARTAMENTO DE ANTIOQUIA: Municipio Maceo, vereda Las Brisas, Quebrada Santa Barbara (06°32'38.8"N, 74°38'24.8"W, ca. 500 m elev.). 28 July 2003. Museo de Herpetología Universidad de Antioquia, Medellín, Colombia (MHUA 2676, male) and 20 March 2004 (MHUA 3233, male). All collected by J. C. Arredondo and M. Rivera-C. and verified by J. D. Lynch. Adults were found on leaf litter at the edge of a stream in secondary forest. This species is distributed disjuntly in western Panamá and in Colombia (Kluge 1979. Occas. Pap. Mus. Zool. Univ. Michigan 688:1–23). Previously known only from the following localities in Colombia: Socorro, upper Río Sinu (Cordoba Department); Lower Río Calima and vereda El Danubio (Valle del Cauca Department); and La Guayacana (Nariño Department) (Kluge, *op.cit.*; Vargas-S. and Castro-H. 1999. Caldasia 21:95–109). First records from Antioquia Department and Colombian Cordillera Central, extend the distribution toward the eastern region of Colombia and fill a hiatus between its nearest known localities (ca. 215 km SE from Cordoba Department and ca. 263 km NE from Valle del Cauca Department).

Submitted by **MAURICIO RIVERA-C.** and **PAUL D. A. GUTIÉRREZ-C.**, Grupo Herpetológico de Antioquia (GHA), Instituto de Biología, Universidad de Antioquia, oficina 7-106, A.A. 1226, Medellín, Colombia; e-mail: mauriciorivera79@yahoo.com.ar.

HYLA SAVIGNYI (Savigny's Tree Frog). IRAN: GOLESTAN PROVINCE: MINOUDASHT CITY, Safi Abad Village: 37°10'08"N, 55°33'12"E, 1200 m asl. 3 March 2004. T. Taymouri. Zoological Museum of Gorgan University (ZMGU) 831. Verified by S. C. Anderson. Found in active posture near the base of a tree, ca. 20 m away from nearest water. First provincial record, and eastward range extension by almost 220 km (Baloutch and Kami 1995. Amphibians of Iran, p. 148. Tehran University Press, Tehran).

OSTEOPILUS SEPTENTRIONALIS (Cuban Tree Frog). BRITISH VIRGIN ISLANDS: TORTOLA: Road Town Dock (18°25.8'N, 64°36.8'W). Fall 1990. Everton Henry. MCZ A-135386. First island record. NECKER ISLAND (18°31.6'N, 64°21.6'W). 19 October 1993. A. Miller. MCZ A-119258. First island record. BEEF ISLAND: Trellis Bay (18°26.44'N, 64°32.08'W). 15 October 2002. Gad Perry and Kate LeVering. MCZ A-136611. First island record. VIRGIN GORDA: Spanish Town (18°26.6'N, 64°26.2'W). 27 October 2003.J im Egelhoff. MCZ A-136432. First island record. All verified by Jose Rosado and deposited at the Museum of Comparative Zoology, Harvard University.

Native to Cuba, the Cayman Islands, and Bahamas, the Cuban Tree Frog (CTF), is recorded as introduced in Florida, Puerto Rico, Hawaii, Costa Rica, and several Caribbean islands including Anguilla and the US Virgin Islands (Lever 2003. Naturalized Reptiles and Amphibians of the World. Oxford University Press, New York. 318 pp; reviewed in Somma at http://nas.er.usgs.gov/queries/SpFactSheet.asp?speciesID=57, accessed 20 August 2004). It has also been collected at multiple North American sites where populations have not been established (Somma, *op. cit.*). The CTF has not previously been formally reported as present in the British Virgin Islands (BVI). However, the Necker specimen has formerly been mentioned by Meshaka (2001. The Cuban Tree Frog in Florida: Life History of a Successful Colonizing Species. Univ. Press of Florida, Gainesville, Florida. 191 pp.) and the presence on Tortola has previously been cited on the internet (G. Perry in Somma, *op. cit.*).

The first collection of the CTF in the BVI was on Tortola in 1990 (MCZ A-135386), and multiple specimens have been collected thereafter. A single specimen was collected on Necker Island in 1993 (MCZ A-119258). However, no viable population was established (Meshaka, *op. cit.*). The CTF appears to continue spreading in the BVI. Breeding populations were recently recorded on Beef Island (2002, beginning with MCZ A-136611) and Virgin Gorda (first collection in 2003, MCZ A-136432). Surveys continue on other islands where it might establish.

The CTF is usually introduced through importation of horticultural or building supplies (Somma, *op. cit.*). BVI resident Elvet Meyers noted (pers. comm.) that CTFs were found in concrete block pallets arriving from Florida directly to Cane Garden Bay, Tortola in April 2000, long after the species was first documented on the island. According to Meyers, local populations then rapidly irrupted, having bred in ghut puddles and a beach lagoon that sometimes contains fresh water. Thus, at least some populations are the result of multiple introduction events, potentially from different sources. The ecological impacts of the CTF remain to be established (Somma, *op. cit.*). However, interviews with BVI residents indicate a decline in native frog populations as the CTF increases in numbers. Concerns thus continue to arise as the CTF expands its range throughout the BVI and the Caribbean.

Support for this project was provided by The Conservation Agency, The Texas Herpetological Society, H. Lavity Stoutt Community College and Texas Tech University. This is manuscript T-9-1027 of the College of Agricultural Sciences and Natural Resources, Texas Tech University.

STERNOTHERUS ODORATUS (Stinkpot). USA: ARKANSAS: POLK CO: Ouachita River at U.S. Hwy. 71 at Acorn. 1 October 2004. Daniel C. Allen. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 28772). Verified by Stanley E.Trauth. New county record in western Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **DANIEL C. ALLEN, HENRY W. ROBISON, JANET RADER,** and **TESS RADER,** Department of Biological Sciences, Southern Arkansas University, Magnolia, Arkansas 71754-9354, USA; e-mail (HWR): hwrobison@saumag.edu.

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider). USA: FLORIDA: ST. JOHNS CO: 6.4 km S of the intersection of A1A South and State Road 206 (29°43'N, 81°13'W) Fort Matanzas National Monument (FOMA). 23 August 2004. Dana J. Ehret and David Parker. Florida Museum of Natural History (UF 142391). Verified by Kenneth L. Krysko. Juvenile, straight carapace length 150 mm. Individual was collected dead on AIA South in front of Ft. Matanzas National Monument, which is located on Anastasia Island. This species is invasive in Florida, but has been documented in a few counties as early as 1958 (Ashton and Aston 1991. Handbook of Reptiles and Amphibians of Florida, Part 2: Lizards, Turtles, and Crocodilians 2nd Edition. Windward Publishing, Inc. Miami, Florida, 191 pp.). This new county record should serve as a reminder to document the spread of introduced species.

Submitted by **DANA J. EHRET**, Florida Museum of Natural History, Dickinson Hall, Museum Road & Newell Drive, PO Box 117800, University of Florida, Gainesville, Florida 32611-7800, USA; and **DAVID PARKER**, Fort Matanzas National Monument, 8635 A1A South St. Augustine, Florida 32080, USA; e-mail dehret@flmnh.ufl.edu.

LACERTILIA

ANOLIS MACULIGULA. COLOMBIA, DEPARTAMENTO DE ANTIOQUIA. Municipio Valdivia, Corregimiento Puerto Valdivia, Vereda La China (7°16'30"N, 75°20'58"W) ca. 600 m elev. 09 May 1997. Museo de Herpetología Universidad de Antioquia, Medellín, Colombia (MHUA 10041, adult male). Captured in gallery forest on rock by a stream. J. M. Daza-R. Verified by F. Castro. This species has been considered endemic to northern Chocoan lowland rainforest in Cordillera Occidental (Williams 1984. Breviora 478:1–22; Uetz 2004. www.embl-heidelberg.de/~uetz/LivingReptiles.html). The present record extends the distribution to the northern part of Cordillera Central almost 190 km NE from its type locality.

Submitted by **JUAN MANUEL DAZA-R.** Grupo Herpetológico de Antioquia, Instituto de Biología, Bloque 7-121, Universidad de Antioquia, A.A. 1226, Medellín, Colombia; e-mail: juandaza35@hotmail.com.

BACHIA BRESSLAUI (Bresslau's Bachia). BRAZIL: MATO GROSSO DO SUL: MUNICIPALITY OF AQUIDAUANA: Dois Irmãos do Buriti district: Santa Helena farm (20°31'00"S; 55°20'15"W) a Cerrado fragment of about 200 ha. 24 November 2003 and 08 February 2004. Zoology Collection, Laboratório de Zoologia, Campus de Corumbá, Universidade Federal de Mato Grosso do Sul, Corumbá, Mato Grosso do Sul, Brazil (CEUCH 2998, CEUCH 3270). Both captured in pitfall traps with drift fence. N.C. Cáceres and collaborators. Verified by R. W. Avila. *Bachia bresslaui* is a rare gymnophthalmid known only from Cerrado of central-west Brazil (Chapada dos Guimarães, MT, Brasília, DF), NE Bahia (Correntina), and possibly SE (São Paulo) by Colli et al. (1998. Herpetologica 54:169–174). This first state record for the genus extends the known distribution ca. 540 km S from Chapada dos Guimarães, Mato Grosso state and 870 km SW from Brasília, Distrito Federal.

Submitted by **VANDA LÚCIA FERREIRA**, **DENISE MIGUEL PETRONI,** Lab. de Zoologia, Campus de Corumbá, Universidade Federal de Mato Grosso do Sul, Caixa Postal 252, CEP 79301-970, Corumbá, MS, Brazil (e-mail: vandaf@ceuc.ufms.br; depetroni@bol.com.br); and **NILTON CARLOS CÁCERES,** Depto. CYRTOPODION CASPIUM CASPIUM (Caspian Bent-toed Gecko, or Caspian Thin-toed Gecko). IRAN: MAZANDARAN PROVINCE: Ghaemshahr City: ca. 36°28'00"N, 52°51'45"E, 40 m elev. 1994 (exact date unknown). S. Mirzanejad. Zoological Museum of Gorgan University (ZMGU 71). Same locality. 31 March 2004. E.Samadian. ZMGU 836. Feridounkenar City, ca. 36°41'N, 52°31'E, 24 and 30 October 2003. A. Pourmomeni. ZMGU 751–758. Collected at night on the walls of buildings. Verified by S. C. Anderson. First provincial records and westernmost records of the species in Iran. This gecko is very common in Bandar-e-Turkmen. In Iran it is known from the Gorgan region of Golestan Province, from the northern part and Khorasan, extending southward to Sistan. The historical altitudinal distribution of this species in Iran was from sea level to 1700 m (Anderson 1999. The Lizards of Iran, p. 156. SSAR, St. Louis). Specimens from Feridounkenar City were found at -20 m asl., extending the lower altitudinal limit by 20 m.

EUMECES LATICEPS (Broad-headed Skink). USA: ARKANSAS: Madison Co: Madison County Wildlife Management Area. 15 June 2001. Voucher specimen in Arkansas State University Museum of Zoology (28590). Verified by Stanley E. Trauth. First county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **CHAD E. MONTGOMERY** and **STEVEN J. BEAUPRE**, University of Arkansas, Department of Biological Sciences, Fayetteville, Arkansas 72701, USA; e-mail: chad_mont@yahoo.com.

HEMIDACTYLUS TURCICUS (Mediterranean House Gecko). USA: CALIFORNIA (as listed below). In California, *Hemidactylus turcicus* was first reported from Ocotillo in Imperial County (Porter 1988. San Diego Herpetol. Soc. Newsl. 10:5; LACM 137493–95). Sight records were reported from Cathedral City and Palm Springs, Riverside Co. (Cornett 1997. The Desert Sun, January 5, 1997) and the species was included in a checklist of the amphibians and reptiles of California based on records from El Centro, Imperial County (Laudenslayer et al. 1991. California Fish and Game 77[3]:109–141 [see Saethre and Medica 1993. Herpetol. Rev. 24:154–155]). Voucher specimens for El Centro and Palm Springs were obtained, herein reported as LACM 153060 and LACM 147938, respectively.

The following records are new for California: Imperial Co: Brawley (LACM 155072); Riverside Co.: Blythe (LACM 146690), Desert Hot Springs (LACM 146693), Indio (LACM 155073), Palm Desert (LACM PC 1386), and Rancho Mirage (LACM 152669); San Bernardino Co: Earp (LACM 146691) and Needles (LACM 155124); and San Diego Co: El Cajon (LACM-PC 1363). Verified by Andrew G. Gluesenkamp. Searches of residential and commercial areas in Coachella, Holtville, La Quinta, Mecca, and Thermal were unsuccessful. Our records suggest a very localized distribution. Mediterranean House Geckos have been observed at Moorten Botanical Gardens in Palm Springs for approximately 25 years (J. Moorten, pers. comm.). The species also occurs in nearby neighborhoods, but is apparently absent from other suitable areas. Probable dispersal mechanisms for this species in California include transportation of nursery stock, transport via recreational vehicles and associated equipment (e.g., a specimen was found in the folds of a canvas picnic umbrella) and the use of railroad ties for landscaping (e.g., specimens were found in the crevices of railroad ties at two localities).

The Mediterranean House Gecko is one of two introduced species of gecko that have become established in California. A population of the Common Wall Gecko (*Tarentola mauritanica*) has been reported from San Diego County (Mahrdt 1998. Herpetol. Rev. 29:52). The impact of *H. turcicus* on native gecko populations (e.g., *Coleonyx* and *Phyllodactylus*) is unknown.

SCINCELLA MODESTA (Slender Forest Skink). CHINA: GUANGDONG PROVINCE: HUADU Co: Wang Zi Feng (Princess Peak). 19 July 2004. Wenhua Lu. Verified by Zhen-chang Li, South China Normal University (SCNU), Guangzhou, Guangdong, China. SCNU 4070. Young of the year. New county record. "Has a puzzling distribution in central and southern China that is rather discontinuous" (Karsen et al. 1998. Hong Kong Amphibians and Reptiles. Second edition. Provisional Urban Council, Hong Kong, China, 186 pp.). Zhou and Adler (1993. Hepetology of China. SSAR, Oxford, Ohio, 522 pp.) did not list this species for either Guangdong Province or Hong Kong. However, *S. modesta* has long been known from the mainland New Territories of Hong Kong and the large islands of Hong Kong and Lantau (Karsen et al. 1986. Hong Kong Amphibians and Reptiles. Urban Council, Hong Kong, 136 pp.). Lazell et al. (1997. Asiatic Herpetol. Res. 7:80–84) recorded *S. modesta* on Wai Ling Ding in the Wanshan Archipelago of Guangdong. This little-known and uncommon skink is of considerable biogeographic interest because of its close resemblance to *S. laterale* of southeastern North America (Lazell and Lu 2003. *In* X. Pang [ed.], Studies on Biodiversity of the Guangdong Nanling National Nature Reserve, pp. 65–88. Guangdong Science and Technology Press, Guangzhou, China).

CYLINDROPHIS RUFFUS (Red-tailed Pipe Snake). VIETNAM: QUANG BINH PROVINCE: Vicinity of Dong Hoi. July 2004. Collected by local people. Zoologisches Forschungsinstitut und Museum Alexander Koenig, Bonn, Germany (ZFMK 82922). Verified by Wolfgang Böhme. *Cylindrophis ruffus* was previously only known from a few provinces in central and southern Vietnam, northwards up to Quang Tri (Nguyen Van Sang and Ho Thu Cuc 1996. Danh luc bo sat va ech nhai Viet Nam. Nha xuat ban khoa hoc va ky thuat, Ha Noi), as well as from Tam Dao mountain ridge in the northern part of the country (Orlov et al. 2000. Russ. J. Herpetol. 7:69–80). This specimen represents the first record for the Quang Binh Province, which borders Quang Tri Province in the south. The specimen (SVL 670 mm; TL 13 mm) exhibits coloration, patterning and scale counts diagnostic for the species. It was caught in a rice paddy near the sea.

SINONATRIX AEQUIFASCIATA (Equal-banded Watersnake). VIETNAM: NGHE AN PROVINCE: Vicinity of Ky Son. November 1986. Hoang Xuan Quang and students. Zoologisches Forschungsinstitut und Museum Alexander Koenig, Bonn, Germany (ZFMK 82923). Verified by Wolfgang Böhme. *Sinonatrix aequifasciata* had long been known only from southern China (Zhao and Adler 1993. Herpetology of China. SSAR, Oxford, Ohio). Recently, Orlov et al. (2000. Russ. J. Herpetol. 7:69–80) recorded the species from Tam Dao Mountain Ridge for the first time for Vietnam, and stated that it occurs in central and northern Vietnam but without referring to any concrete evidence. This specimen represents the first voucher for the Nghe An Province. This juvenile (SVL 170 mm; tail 54 mm) exhibits coloration, pattern (23 dark dorsal bands on body, 13 on tail), and scale counts characteristic of *S. aequifasciata*.

Submitted by **THOMAS ZIEGLER**, Zoologischer Garten Köln, Riehler Str. 173, D-50735 Köln, Germany (e-mail: tziegler@zoo-koeln.de); and **HOANG XUAN QUANG**, University of Vinh, Nguyen Du Str., Vinh - Nghe An, S. R. Vietnam.

SISTRURUS MILIARIUS STRECKERI (Western Pigmy Rattlesnake). USA: ARKANSAS: MADISON CO: Madison County Wildlife Management Area. 26 August 2003. Voucher specimen in Arkansas State University Museum of Zoology (28593). Verified by Stanley E. Trauth. First county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **CHAD E. MONTGOMERY** (e-mail: chad_mont@yahoo.com) and **STEVEN J. BEAUPRE**, University of Arkansas, Department of Biological Sciences, Fayetteville, Arkansas 72701, USA.

STORERIA DEKAYI TEXANA (Texas Brownsnake). USA: TEXAS: LEE CO: Road FM 1624, 1.1 rd mi SW of Lee Co. Road 323 (ca. 3 mi SW of Lexington). 14 September 2003. 190 + 30 mm, 2.8 g. Male collected DOR. TNHC 63074 (GBP 327). Verified by Travis J. LaDuc. New county record and fills a gap within the known distribution (Dixon 2000. STORERIA DEKAYI WRIGHTORUM (Midland Brownsnake). USA: ARKANSAS: LOGAN CO: 10.4 km SW Booneville on St. Hwy 23 (Sec. 30, T5N, R28W). 20 November 2004. H. W. Robison and Janet Rader. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 28814). Verified by Stanley E.Trauth. New county record in western Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville, 421 pp).

Submitted by **HENRY W. ROBISON** (e-mail: hwrobison@saumag.edu) and **JANET RADER**, Department of Biological Sciences, Southern Arkansas University, Magnolia, Arkansas 71754-9354, USA.

STORERIA OCCIPITOMACULATA (Red-bellied Snake). USA: GEORGIA: EARLY CO: 85°0'43"W, 31°24'47"N. 13 March 2002. T. Muenz and L. Smith, Joseph W. Jones Ecological Research Center. GMNH 49907. Verified by J. Jensen. Individual found under log within the riparian area of a second-order stream. This locality represents a new county record (Williamson and Moulis 1994. Distribution of Amphibians and Reptiles in Georgia. Savannah Sci. Mus. Spec. Publ. No.3, 712 pp.).

Submitted by **TARA K. MUENZ** and **LORA L. SMITH,** Joseph W. Jones Ecological Research Center, Newton, Georgia 39870, USA; e-mail (TKM): tmuenz@jonesctr.org.

THAMNOPHIS PROXIMUS (Western Ribbon Snake). USA: TEXAS: JIM HOGG CO: Agua Nueva: Farm Road 1017, 28.8 mi. S jct Hwy 285. 5 June 2004. Thomas A. Sinclair. Verified by James R. Dixon. Texas Cooperative Wildlife Collection-Texas A&M University and Travis J. LaDuc. Texas Natural History Collections-Texas Memorial Museum-University of Texas (TNHC 63006) digital photo. New county record (Dixon 2000. Amphibians and Reptiles of Texas. Second Edition. Texas A&M University Press, College Station, Texas, 421 pp.). This individual fills a gap in the distribution as all counties surrounding Jim Hogg have multiple records from them.

Submitted by **THOMAS A. SINCLAIR**, 12903 Cloverwood Drive, Cypress, Texas 77429-2028, USA (e-mail: tsinclair2@houston.rr.com); and **BOB L. TIPTON**, 15622 Ten Oaks, Tomball, Texas 77377, USA (e-mail: btipton@ghg.net).

THAMNOPHIS SIRTALIS SIRTALIS (Eastern Gartersnake). USA: ARKANSAS: MADISON CO: DOR on Madison County Wildlife Management Area. 7 May 2000. Voucher specimen in Arkansas State University Museum (28596). Additional specimen located near pond on County Road 6060 near Huntsville (N36°4.035', W93°44.189'). 25 April 2004. ASUMZ photo voucher 28712. Verified by Stanley E. Trauth. First county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **STEVEN J. BEAUPRE**, University of Arkansas, Department of Biological Sciences, Fayetteville, Arkansas 72701, USA; **KORY ROBERTS**, Arkansas Herpetological Society, 8 Castle Acre Lane, Bella Vista, Arkansas 72714, USA; and **CHAD E. MONTGOMERY**, University of Arkansas, Department of Biological Sciences, Fayetteville, Arkansas 72701, USA (e-mail: chad_mont@yahoo.com).

TROPIDOCLONION LINEATUM (Lined Snake). USA: NEW MEXICO: CURRY CO: DOR on Curry Co. Hwy 17, 3.2 rd km E NM Hwy 209; ca. 11.3 air km N of Clovis; 1305 m elev. 34°30.24'N, 103°4.40'W. 27 October 2004. James D. Jones.University of New Mexico Museum of Southwestern Biology (MSB 71665).Verified by J. Tomasz Giermakowski. New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque, xix + 431 pp.).

Submitted by **JAMES D. JONES**, 117 East Christopher, Clovis, New Mexico 88101,USA; and **CHARLES W. PAINTER**, New Mexico Department Game and Fish, 1 Wildlife Way,Santa Fe, New Mexico, USA (e-mail: cpainter@state.nm.us).

VIRGINIA VALERIAE ELEGANS (Western Smooth Earthsnake). USA: TEXAS: CASS CO: off St. Hwy 43 in Atlanta, Atlanta City Park. 31 October 2004. J. Caldwell. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 28777). Verified by Stanley E. Trauth. First record for county and extends range north and northeast from previous records in Gregg, Harrison, and Rains counties (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Univ. Press, College Station. 421 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. of Texas Press, Austin, 437 pp.). Although this site is the northeasternmost locality noted for the species in Texas, a single record was reported due east in adjacent Miller County, Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville, 421 pp.). Locality records within its projected range in Texas are relatively uncommon (see Dixon 2000, *op. cit.*) as evidenced by this snake now being reported from only 30 counties.

Submitted by **JENNIFER CALDWELL** and **CHRIS T. McALLISTER,** Department of Biology, Texas A&M University-Texarkana, Texarkana, Texas 75505, USA; e-mail: chris.mcallister@tamut.edu.

Florida has a well-documented herpetofauna, and its exotic herpetofauna has grown considerably over the last few decades since the classic reviews by King and Krakauer (1966) and Wilson and Porras (1983). Florida's diverse habitats, warm climate, and thriving pet trade have facilitated the establishment and subsequent range expansion of many exotic herpetofaunal species. While conducting surveys throughout Florida from May 2000 through October 2003, we documented new county records for both native and exotic species. Additional new county records were obtained from specimens collected or photographed by others and deposited in the Florida Museum of Natural History (FLMNH, UF collection), Louisiana State University Museum of Natural Science (LSUMZ), and Texas Cooperative Wildlife Collection (TCWC). Identification of all UF specimens was verified by K. L. Krysko, unless otherwise noted. Common names follow Crother (2000).

Anura

Bufo marinus (Cane Toad). OKEECHOBEE CO: Okeechobee, Flamingo Motel, 4101 U.S. Hwy. 441 S (27°12.47'N, 80°49.78'W). 30 May 2002. K. L. Krysko and K. M. Enge. UF 132733–34. New county record. Along building at 2030 h.

Hyla gratiosa (Barking Treefrog). GADSDEN CO: Frank Smith Rd. 0.2 km NE of jct. Co. Rd. 159 (30°40.15'N, 84°28.59'W). 4 June 2003. K. M. Enge. UF 137127. New county record. On road at 2200 h.

Osteopilus septentrionalis (Cuban Treefrog). ALACHUA CO: Gainesville, near 4455 SW 34th St. (29°36.80'N, 82°22.32'W). 2 October 2002. J. H. Townsend and D. T. Vergara. UF 134294. New county record. On gutter drain at 2045 h. BAY CO: Lynn Haven, Aberdeen Loop (30°13.71'N, 85°37.17'W). 2 December 2004. S. Wilson. UF 142698. New county record. COLUMBIA CO: O'Leno State Park. May 2001. G. Davidson. UF 122901. New county record. Near bath house in Magnolia area. DUVAL CO: Jacksonville, Mandarin, 10767 Orchard Walk Place West near San Jose Blvd. and I-295 (30°10.84'N, 81°37.34'W). 11 May 2002. D. Burger. UF 137173 (photographic voucher). Jacksonville, 7120 Pottsburg Dr. (30°17.56'N, 81°35.15'W). 17 June 2002. L. Jacobson. UF 133206 (photographic voucher). In koi pond. New county records. FLAGLER CO: Palm Coast, 17 Blaketown Place. 2 November 2004. J. Kuypers. UF 142584 (photographic voucher). New county record. Under the cover of grill on backyard deck at 1700 h. Two others found 16 November 2004.

Rana capito aesopus (Florida Gopher Frog). GLADES CO: ca. 12.5 km WNW of Palmdale (26°59.66'N, 81°26.20'W). 9 May 2000. K. M. Enge and R. T. Felix. UF 137113 (photographic voucher). New county record. In mouth of active gopher tortoise (*Gopherus polyphemus*) burrow in scrubby flatwoods.

Caudata

Notophthalmus perstriatus (Striped Newt). LAKE CO: Ocala National Forest, ca. 3 km SW of Alexander Springs. 17 January 2003. S. A. Johnson and C. Sekerak. UF 135125. New county record. In isolated wetland pond in longleaf pine (*Pinus palustris*) sandhill habitat.

Siren intermedia (Lesser Siren). SUWANNEE CO: Ichetucknee River, just downstream from Devil's Eye Spring mouth (29°58.42'N, 82°45.58'W). 11 December 2001. S. J. Walsh, J. D. Williams, R. J. Lewis, and S. Cole. Verified by P. E. Moler. UF 133883. New county record.

Lacertilia

Agama agama (African Rainbow Lizard). CHARLOTTE CO: Punta Gorda, State Rd. 17 ca. 1.3 km W of I-75 (26°56.46'N,

82°01.89'W). 3 June 2003. K. L. Krysko, C. S. Samuelson, B. L. Talley, K. L. Bell, and F. W. King. UF 137017. Adult female on wall of Circle K store; two other adults observed here, and six adults observed at another site in the area. Punta Gorda, Lavilla Rd. under State Rd. 17 (26°56.37'N, 82°01.64'W). 4 June 2003. UF 137043–55. Ten adults and two hatchlings collected, and ≥ 13 more adults observed. Thirteen adults and one hatchling observed at two other nearby sites, indicating a well-established population. New county records. MIAMI-DADE Co: Homestead, Redland Middle School, Coconut Palm Dr. (SW 248 St.) and SW 162 Ave. (25°32.17'N, 80°27.13'W). 28 March, 29 May, 19 September 2002. K. L. Krysko, K. M. Enge, F. W. King, and W. B. Love. UF 131521, 132696–700, 134222. First records of an undocumented population in Miami-Dade County, although an extirpated population has been reported (Wilson and Porras, *op cit.*; LSUMZ 36647, UF 43490). Numerous individuals observed one to three blocks in each direction. SEMINOLE Co: Sanford, 3000 S Orlando Dr. (28°46.18'N, 81°16.84'W). 26 May 2003. K. L. Krysko and K. M. Enge. UF 136983–88. New county record. Nineteen individuals of both sexes observed in the area.

Ameiva ameiva (Giant Ameiva). BROWARD Co: Deerfield Beach, 90 SE 3rd Ct., just N of SE 4th St. (26°18.75'N, 80°6.177'W). 25 May 2004. K. L. Krysko and K. M. Enge. New county record. Several individuals observed along RR track at 0945 h; population present at least 6 yr.

Anolis cybotes (Large-headed Anole). MARTIN Co: Port Mayaca (26°58.43'N, 80°36.76'W). 25, 28 March 2002. K. L. Krysko, K. M. Enge, F. W. King, and W. B. Love. UF 131446–48, 131527–29. New county record. On fig (*Ficus* sp.) trees.

Anolis equestris (Knight Anole). MARTIN Co: Port Mayaca (26°58.43'N, 80°36.76'W). 25, 28 March 2002. K. L. Krysko, K. M. Enge, F. W. King, and W. B. Love. UF 131449, 131530. New county record. On cypress (*Taxodium* sp.) trees. PALM BEACH Co: Boca Raton, near jct. NE Spanish River Blvd. and State Rd. A1A (26°23.13'N, 80°04.02'W). 2 August 1997. L. Monroe. Verified by R. K. Vaughan. TCWC 80508. New county record. In bush near beach. Documented also in West Palm Beach in January 2003 (UF 137015, photographic voucher). ST. LUCIE Co: E of Carlton Rd. ca. 1.6 km N of Glades Cutoff Rd. (27°16.72'N, 80°32.29'W). 18 August 2003. G. J. Ward and M. A. Flowers. UF 137459. New county record. Seven additional juveniles and adults observed in Brazilian pepper (*Schinus terebinthifolius*) and slash pine (*Pinus elliottii*) trees.

Basiliscus vittatus (Brown Basilisk). COLLIER Co: Naples, Vanderbilt Beach Park (26°15.20'N, 81°49.31'W). 27 July 2002. Jason C. Seitz. UF 137035. 1 September 2002. Jason C. Seitz. UF 137036. 4 June 2003. K. L. Krysko, F. W. King, C. S. Samuelson, B. L. Talley, and K. L. Bell. UF 137034. All specimens collected on mangrove trees and edge of canal along parking lot; numerous other individuals (neonates to large adults) observed during these and other dates. Golden Gate, jct. SW 17th St. and 16th Ave. (26°11.91'N, 81°38.44'W). 23 May 2004. S. Chrzanowski. UF 141603. Numerous other individuals observed along banks of canal. New county records. PALM BEACH Co: Loxahatchee, 16700 W Jenny Ln. (26°42.30'N, 80°18.63'W). 4 July 2003. J. H. Altman. UF 137179–80 (photographic vouchers). New county record. Male and female in backyard. ST. LUCIE Co: N end of Co. Rd. 609 (Header Canal Rd.; 27°28.22'N, 80°29.85'W). 19 August 2003. G. J. Ward, M. A. Flowers, K. L. Krysko, and K. M. Enge. UF 137407, 137447. New county record. Four juveniles and adults observed at 2100 h.

Gekko gecko (Tokay Gecko). LEE Co: Fort Myers (26°40.96'N, 81°48.13'W). 25 June 2002. K. L. Krysko, K. M. Enge, F. W. King, and W. B. Love. UF 133237–39. New county record. MONROE Co: Key Largo, near John Pennekamp Coral Reef State Park (25°07.35'N, 80°24.54'W). April 2002. J. Duquesnel. UF 132435–36. Little Torch Key (24°39.94'N, 81°23.41'W). 3 May 2002. K. L. Krysko and A. N. Hooper. UF 132446. Plantation Key, on Sioux St. E of Indian Mound Trail (24°59.12'N, 80°32.88'W). 3 January 2003. K. L. Krysko. UF 135122–23. New county records.

Hemidactylus frenatus (House Gecko). BROWARD Co: Hollywood, S side of Stirling Rd. just E of jct. NW 65th Ave. (26°02.76'N, 80°13.15'W). 22 August 2003. K. M. Enge and K. L. Krysko. UF 137408. New county record. At least 24 other individuals observed on walls.

Hemidactylus garnotii (Indo-Pacific Gecko). LAKE Co: Leesburg, 6510 Tuscawilla Drive (28°48.042'N, 81°50.938'W). 6 October 2004. K. L. Krysko. UF 142048. New county record (see Townsend and Krysko 2003). On wall at 2230 h; at least 20 more individuals observed in neighborhood.

Hemidactylus mabouia (Amerafrican House Gecko). COLLIER Co: Marco Island, Marco Island Chamber of Commerce office complex at jct. of North Collier Blvd. and Rose Ave. (25°57.30'N, 82°43.03'W). 14 July 2003. T. S. Campbell. UF 137277–85. Island range extension (see Klowden 2002). HENDRY Co: E side of Co. Rd. 832 (Evercane Rd.) at RR tracks (26°42.64'N, 80°54.09'W). 11 March 2003. K. L. Krysko. UF 136077. New county record. Under bark of Australian pine tree (*Casuarina equisetifolia*). MARTIN Co: Tequesta, N side of Loxahatchee River (26°58.48'N, 80°5.31'W). 25 March 2002. K. L. Krysko, K. M. Enge, and F. W. King. UF 131455–56. New county record. OSCEOLA Co: Canoe Creek Service Plaza, Florida Turnpike (28°05.81'N, 81°16.62'W). 22 August 2003. K. L. Krysko and K. M. Enge. UF 137421–24. New county record. PALM BEACH Co: Jupiter, ca. 1.6 km W of U.S. Hwy. 1, 4.8 km S of Martin Co. line (26°55.64'N, 80°5.62'W). 6 April 2001. C. Roelke. UF 122899–900. New county record.

Hemidactylus turcicus (Mediterranean Gecko). BAKER Co: Macclenny, 682 W Ohio Ave. (30°17.08'N, 82°07.10'W). 3 October 2003. D. Davis. UF 138388. New county record (see Townsend and Krysko, *op cit.*). Inside house; two other adults seen on outside wall at night. PASCO Co: Dade City, 37715 Farr Rd. (28°56.63'N, 82°11.50'W). 9 November 2004. C. Henderson. UF 142582 (photographic voucher). New county record (see Townsend and Krysko, *op cit.*). Found underneath wooden pallets in yard. VOLUSIA Co: Daytona Beach, W side of State Rd. A1A (N Atlantic Ave.) N of jct. Earl St. (29°13.81'N, 81°00.62'W). 15 August 2003. K. L. Krysko, K. M. Enge, and A. N. Hooper. UF 137426–7. New county record (see Townsend and Krysko, *op cit.*).

Iguana iguana (Common Green Iguana). COLLIER Co: Golden Gate, 1716 SW 46th St. SW (26°11.74'N, 81°42.04'W). 1998. S. Chrzanowski. UF 141486 (photographic voucher). New county record. In cypress tree; a few other individuals observed along canal. LEE Co: Cape Coral (26°33.75'N, 81°57.81'W). February

2000. J. Hollister and L. Hollister. UF 133209 (photographic voucher). New county record. Monroe Co: Upper Sugarloaf Key, 940 Loggerhead Lane (24°40.33'N, 81°32.15'W). 29 December 2001. K. L. Krysko and S. W. Morey. UF 131549 (photographic voucher). Four individuals observed feeding on a dock along a canal. 2 January 2002. UF 134836. Subsequent specimen collected. Stock Island, Key West Botanical Garden (24°34.41'N, 81°44.99'W). 7 August 2002. K. L. Krysko and A. N. Hooper. UF 133862 (photographic voucher). On buttonwood (*Conocarpus erectus*) tree. Little Torch Key (24°40.39'N, 81°23.41'W). 5 July 2003. K. L. Krysko. UF 137214. Hatchling on grass at base of *Conocarpus erectus*. Two other hatchlings and six adults observed within 100 m along canal. New county records. Palm Beach Co: Palm Beach Gardens, 2427 Marseilles Dr. (26°52.73'N, 80°04.38'W). March 2003. G. Ramseier. UF 137086 (photographic voucher). Female on floating platform in water. Documented also in Loxahatchee in July 2003 (UF 137181, photographic voucher). New county records.

Leiocephalus carinatus (Northern Curly-tailed Lizard). Monroe Co: Key Largo, Buttonwood Bay, 96000 Overseas Hwy (25°03.93'N, 80°28.46'W). 21 August 2003. K. L. Krysko, K. M. Enge, D. Giardina, and J. G. Duquesnel. UF 137527–28. New county record. Palm Beach Co: Belle Glade, 324 State Rd. 715 ca. 100 m N of Florida East Coast RR tracks (26°41.51'N, 80°41.05'W). 15 August 2002. T. S. Campbell. UF 134110–11. Represents an independent introduction ca. 65 km W of the Palm Beach population along the Atlantic Coast (King and Krakauer 1966; Wilson and Porras, *op cit.*). Numerous individuals of all size classes were observed on sidewalks, landscaping, and vegetation around the main entrance to the building and along the fence line N of the RR tracks.

Leiocephalus schreibersii (Red-sided Curly-tailed Lizard). Charlotte Co: Punta Gorda, State Rd. 17 ca. 1.3 km W of I-75 along N edge of right-of-way at S end of Solona Loop W (26°56.48'N, 82°01.87'W). 19 June 2003. T. S. Campbell. UF 137133–34. New county record; this locality is ca. 210 air km NW of the nearest reported population in Broward County (Townsend et al. 2002). Three adults and numerous hatchlings observed in sandy areas along fence line and on Solona Loop W.

Serpentes

Heterodon platirhinos (Eastern Hog-nosed Snake). Hernando Co: Croom Wildlife Management Area (28°33.19'N, 82°15.89'W). 29 March 2004. D. Smith. UF 141651 (photographic voucher). New county record. In former sandhill habitat among planted longleaf pine seedlings.

Ramphotyphlops braminus (Brahminy Blind Snake). Brevard Co: Eau Gallie, 4326 Sherwood Blvd. (28°10.63'N, 80°39.65'W). 15 October 2004. K. Pennick. UF 142697 (photographic voucher). New county record. Between the drywall and concrete block of a house. Citrus Co: Inverness, 804 Windy Avenue (28°49.29'N, 82°20.02'W). 29 August 2003. C. Fitzgerrell. UF 137720. New county record. Found inside house along with two other specimens. Collier Co: Marco Island, Hideaway Beach (25°57.53'N, 81°44.82'W). 21 November 2002. J. C. Seitz. UF 137071. New county record. Leon Co.: Tallahassee, Killearn Estates, Arklow Dr. near Tralee Rd. (30°31.25'N, 84°11.94'W). 29 March 2001. D. G. Cook. UF 140540. DOR. Tallahassee, Killearn Estates, 4130 Arklow Dr. (30°31.29'N, 84°11.98'W). 6 July 2002. D. G. Cook. UF 140541. DOR. New county records.

Seminatrix pygaea (Swamp Snake). Washington Co: State Rd. 90, 0.2 km W Holmes Co. line (3°47.32'N, 85°45.38'W). 27 April 2001. P. E. Moler. UF 123185. New county record.

Storeria victa (Florida Brownsnake). Manatee Co: Buckeye Road (27°37.41'N, 82°31.98'W). October 2002. L. Pike. UF 141264. New county record.

New Distributional Records of *Ambystoma talpoideum* (Caudata: Ambystomatidae) in Southwestern Arkansas

BRIAN CALDWELL
and
RENN TUMLISON
Department of Biological Sciences, Henderson State University Arkadelphia, Arkansas 71999, USA
e-mail (RT): tumlison@hsu.edu

Populations of *Ambystoma talpoideum* in southwestern Arkansas appear to be isolated or disjunct from populations in northern Louisiana, northeastern Texas, and eastern Oklahoma (Conant and Collins 1998; Petranka 1998; Trauth et al. 1993), and available information seldom defines whether populations are metamorphic or paedomorphic. Recent records (Caldwell and Tumlison 2003; Tumlison and Campbell 2002) prompted a survey for *A. talpoideum* in southwestern Arkansas, outside of its previously known range. Using dipnets and seines, we sampled aquatic habitats because aquatic *A. talpoideum* are more easily captured than the burrowing terrestrial adults (Bishop 1947).

Habitat descriptions (Bishop 1947; Dundee 1989; Petranka 1998) directed us to suitable sampling sites. Topographic and county maps were used to locate wooded, swampy, and lowland areas, then roads were cruised in those areas to identify specific sampling sites. At each site, several net drags were used to sample the pool.

Sampling from April 2002 to May 2004 produced several new records of *Ambystoma talpoideum* from the southwestern Arkansas region. Voucher specimens are housed in the Henderson State University (HSU) Vertebrate Collections in Arkadelphia, Arkansas. Identification of metamorphic and paedomorphic forms was aided by the photographs in Trauth et al. (2004), and verified by Stan Trauth. Metamorphic salamanders were collected from temporary pools. Paedomorphic forms were collected in small, permanent, fishless ponds.

CLARK Co., 8 km NW Gurdon (S27 T9S R21W), 23 February 2002 and 15 March 2002, Renn Tumlison, HSU 903–906, 1281. Only paedomorphic larvae (numerous) were found in one pond, and a single metamorphic form (1281) was taken from another pond located about 1 km distant. Center Grove Church Road, 0.8 km E Hwy 182 (S1 T9S R22W), 24 March 2002, Tobin Fulmer, HSU 1041, paedomorphic larvae. 10 km W Hollywood, Hwy 26 (S3 T8S R22W), 15 May 2002 and 26 April 2003, Brian Caldwell, HSU 1278, 1299, metamorphic larvae.

COLUMBIA Co., 3 km E McNeil (S16 T16S R20W), 25 April 1992, Renn Tumlison, HSU 1282, metamorphic larvae.

DALLAS Co., jct. Co. Rds. 245 and 247 (S6 T9S R17W), 22 April 2003, Brian Caldwell and Tobin Fulmer, HSU 1293, metamorphic larvae; 3.7 km S Ouachita, Hwy 7 (S34 T10S R17W), 22 April 2003, Brian Caldwell and Tobin Fulmer, HSU 1294, metamorphic larvae.

HEMPSTEAD Co., Co. Rd. 32, 0.6 km from jct. with Co. Rd. 27 (S9 T9S R26W), 26 April 2003, Brian Caldwell, HSU 1295, metamorphic larvae.

HOWARD Co., 5 km W jct. Hwys 26 and 369, (S30 T8S R27W), 27 and 28 April 2003, Brian Caldwell, HSU 1297, 1302, metamorphic larvae.

PIKE Co., 3 km SW of Murfreesboro, off Hwy 27 (S14 T8S R26W), 27 April 2002 and 26 April 2003, Brian Caldwell and Tobin Fulmer, HSU 1274, 1300, metamorphic larvae; NW of Murfreesboro (S3 T8S R26W), 4 May 2002, Brian Caldwell, HSU 1275, metamorphic larvae; 6 km SE of Murfreesboro, Hwy 301 (S6 T9S R24W), 5 May 2002, Brian Caldwell, HSU 1276, metamorphic larvae; 11 km SE of Murfreesboro, Hwy 301 (S15 T9S R24W), 15 May 2002, Brian Caldwell, HSU 1277, metamorphic larvae; 5 km SW of Murfreesboro, Hwy 27 (S23 T8S R26W), 15 May 2002, Brian Caldwell, HSU 1279, metamorphic larvae; 2.9 km SW Nathan, Co. Rd. 7 (S6 T8S R26W), 26 April 2003, Brian Caldwell, HSU 1296, metamorphic larvae; 1 km E jct. Hwys 29 and 301 (S35 T8S R23W), 9 May 2003, Brian Caldwell, HSU 1305, metamorphic larvae.

Acknowledgments.—We thank Stan Trauth for verifying identification of specimens, Fred Kizzia for permission to collect on his land, and Tobin Fulmer for field assistance.

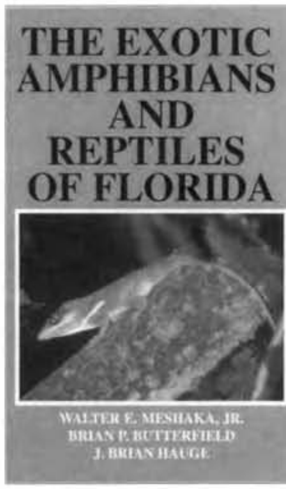
e-mail: dfranz@flmnh.ufl.edu



The presence of invasive species can potentially pose a severe threat to a region's biodiversity by altering natural landscapes and affecting its native biota. As an example, with just a quick trip through southern Florida, one can appreciate the dramatic environmental damages from invasive plant species. The impacts of introduced animals are often less visible, except when they become agricultural pests or nuisances. Although exotic amphibians and reptiles have been present in Florida since at least the mid 19th century, they have rarely drawn attention except from the occasional inquisitive citizen, curious about some unrecognized species in his yard.

This book includes an introduction, 40 full accounts of established species, 19 abbreviated accounts of species with uncertain status, an afterword, a glossary, two appendices, and references. The full accounts cover four frog species in three families, one turtle, 32 lizards in five families, two snakes in two families, and a crocodilian. These accounts include a description, information on body size, history of the introduction, current distribution, habitat, habits, reproduction, diet, and potential predators. A section in the full accounts on similar-appearing taxa is meant to separate more difficult species. Color plates and range maps are provided for the established species. The 19 abbreviated accounts provide information on occurrences of species not known to be established and breeding in Florida. A six-page Afterword by Walter Meshaka, entitled "The human role in the colonization of species in Florida," discusses the attributes of a successful colonizing amphibian or reptile species in Florida, the role the exotic plays "in the context of conservation," and recommendations for lessening the impacts of introductions on native species and habitats. Sadly, this section suffers from academic tedium that could have been written in a more inviting style to ensure the readership of the intended audience.

Guides such as this book will always represent a work-in-progress since there is no end in sight to the introduction of novel amphibians and reptiles to Florida. For example, between 2002–2004, more than 35 papers appeared in the literature that reported range extensions, possible extirpations, taxonomic clarifications, and new additions for Florida's exotic herpetofauna. These more recent citations can be found in the online bibliography maintained by the Florida Fish and Wildlife Conservation Commission (www.wildflorida.org/ herpbibl/default.asp). One thing for certain, Florida's list of exotic amphibians and reptiles will continue to expand as more and more species are incidentally or deliberately released in the state, despite state laws that prohibit such activities. As a result, investigating Florida's exotic amphibians and reptiles will remain a fertile field for research for years to come.

For the most part, the book is generally well constructed, easy to read, and contains interesting information. The accounts include numerous literature citations that allow readers to track information. Many of the accounts have tables that provide information on body sizes, activity patterns, reproduction, diet, and perch heights, which in my opinion adds little to the book's overall usefulness. The range maps are well constructed with symbols representing records without voucher specimens or photographs, general distributions, literature records, and unpublished records supported by museum specimens or photographs. The photographs are of mixed quality, although the blame may lie with the printing process rather than with the original photographs taken by many well-known herpetological photographers. One important drawback to the book is the lack of descriptive materials or photographs for reptiles in the abbreviated accounts. It seems to me that this was a missed opportunity to draw attention to species that lack confirmation in the state. The appendices add little to the usefulness of the book. The authors could have used common names throughout the text to improve general readership and depended on Appendix B to convert common and scientific names. A minor irritation…they misspelled *Heterodon platirhinos* in Appendix B.

The book by Meshaka, Butterfield, and Hauge belongs to the genre of the ever-growing field guides that market Florida's rich biota. *The Exotic Amphibians and Reptiles of Florida* will be of interest to those naturalists, particularly in southern Florida, who want to know more about the strange frogs, lizards, and other non-native herpetological species that appear in their neighborhoods. This book can provide them with a wealth of information on the histories that surround the introductions and how the animals came to reside in their backyards. The slim, hardback volume is overpriced, which probably will influence its availability for the people who would be best served by it.

Erratum

In Ken Kawata's article in the last issue of *HR* (vol. 35, number 4, page 317), Charles Shaw was mistakenly credited with bringing the San Diego Zoo's herpetological collection to prominence by 1930. However, the credit should have been given to C. B. "Si" Perkins. Shaw's tenure at the Zoo came much later, serving as Curator of Reptiles from 1954 until his death in 1971.

Arkansas is a state with a large and diverse herpetofauna with over 136 species and subspecies and, until now, it was a state without a field guide to amphibians and reptiles. *The Amphibians and Reptiles of Arkansas* is actually much more than a field guide in respect to both depth of material and size of the book. This book has been in the works for over two decades by the senior author and his efforts show.

The introductory sections of the book include a detailed history of herpetological studies in Arkansas stretching back over 100 years, starting with John Strecker and Julius Hurter in the early 1900s. The section is broken down by decade with each period, especially from 1970s on, showing increased herpetological activity compared to the previous decade. The high level of activity in the last 25 years is largely the result of the work of the authors and their students throughout the state.

"Classification and Species Checklist" shows what happens when multiple names lists are merged. The authors state that they use the scientific names from Crother (2000) and the common names of Conant and Collins (1998) and Collins (1997). They then recognize subspecies in Conant and Collins (1998), which differ from Crother (2000) and use common names found in Crother (2000), but not Collins (1997). I would have liked to see one name list used, preferably the officially recognized list (Crother 2000), since mixing of differing lists may confuse users of the book. Where names differ from the base list, such as competing lists or local names, relevant remarks can be included in the species accounts.

The "Ecoregions of Arkansas" section highlights the diversity of the state, with areas as disparate as the Ozark Highlands and the Mississippi Bottomlands. Topographic relief varies by region with as little as 50 m in the Mississippi Alluvial Plain to almost 800 m in the Arkansas Valley. The six different regions and twelve subdivisions in the state contribute to the high diversity of amphibians and reptiles. The authors do a good job describing the different habitats. This section is illustrated with representative photos of the major ecoregions.

The "Searching for and Observing" section provides good general insights into locating Arkansas herps. The variety of techniques covered goes from the mundane—dipnetting tadpoles from roadside ditches, to the exhilarating—rapids diving for Hellbenders. There are bolded passages throughout the section highlighting the ethical points of collecting. Other authors should highlight these points more often. The Conservation section carries on the theme of ethics. It also shows the authors' concerns about state agency practices that are detrimental to reptiles. These range from cold water discharges from dams to improve trout habitat, which negatively impacts turtles, to the limited regulations on the harvest of amphibians and reptiles, which leaves most of Arkansas' species open for commercial exploitation.

The species accounts constitute the majority of the book. The major groupings are preceded by illustrated keys and followed by keys to the larval forms. The adult keys work well and the line drawings by Renn Tumlison are very well done. The larval keys are the highlight of the book. The keys are illustrated with excellent photos of each species at different stages of development. This is something that is missing in most state amphibian books. The one species with "wow" factor is the gorgeous black-and-orange Bird-voiced Treefrog tadpoles. These are not your grandma's hylid tadpoles!

The accounts are broken down into description, Arkansas distribution, habitat and habits, conservation status and Arkansas literature and remarks. Each account also includes a detailed state distribution map and a generalized map of the national distribution. Multiple color photos accompany each account. Besides having a portrait of the species, the photos show interesting natural history and habitat information. The photos are well composed and large enough to show details. Having color photos throughout the books adds greatly to the user friendliness.

The accounts are complete with much Arkansas-specific data. The one disappointing species account is the Gray Treefrog (*Hyla chrysoscelis/Hyla versicolor*) "sibling species complex." These two species are treated as one, even though they have been known to be separate species, with different calls and habitats, for over 40 years. Several other authors (Collins 1993; Harding 1997; Johnson 2000) have also taken this route, but it is more noticeable here given the separate accounts for the four species in the "*Plethodon albagula* complex." Hopefully, when the authors are ready to do a revision, they will split the Gray Treefrog account.

The closing sections of the book include the most complete Glossary I have seen in a state work and a 28-page Literature Cited with close to 1000 citations. The book also has a large full-page map of the state with county names and major waterways.

The Amphibians and Reptiles of Arkansas has raised the bar for other state amphibian and reptile books. The authors did an excellent job and the book will be indispensable to all herpetologists and conservationists, especially those in Arkansas and surrounding states. I would also strongly recommend it to anyone thinking about writing a book about the amphibians and reptiles of their state or province. This is the new benchmark.

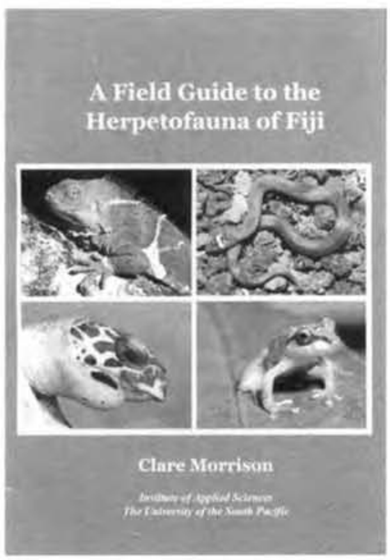
Department of Biology, Villanova University
800 Lancaster Avenue, Villanova, Pennsylvania 19085, USA
e-mail: aaron.bauer@villanova.edu



The Fijian herpetofauna comprises an interesting mix of endemics (including the Fijian iguanas — *Brachylophis*, the elapid *Ogmodon vitianus*, the skink "*Leiolopisma*" *alazon*, and the gecko *Lepidodactylus manni*) and a number of widespread species, both terrestrial and marine. Until now the only major modern work devoted specifically to the herpetofauna of the archipelago has been a technical monograph on the lizards by Zug (1991). Information on other groups (none of which are particularly diverse) may be found in more general works on the amphibians and reptiles of the Pacific or in more narrowly focused papers scattered through the herpetological literature. Thus, *A Field Guide to the Herpetofauna of Fiji* is a book with a niche to fill.

The book begins with a general section on reptiles and amphibians, a brief summary of the Fijian herpetofauna, and a short introduction to the geology, climate and vegetation of the island group. An accompanying reference map for Fiji labels the islands mentioned in the text, but is not particularly well reproduced. This will be sufficient to orient unfamiliar readers, but just barely. The remainder of the book consists of keys (frogs, lizards, snakes, and turtles), each followed by the relevant species accounts, organized alphabetically by genus and species regardless of family. Thirty terrestrial and nine marine species recorded from Fiji are treated, including introduced species, such as *Bufo marinus*, and apparent vagrants, such as *Lepidochelys olivacea*, which has been reported from only a single locality. The only omission appears to be *Crocodylus porosus*, which has been recorded as a stray stranding on Rotuma at least once in historical times (Gardiner 1919). Each account provides Latin, English, and Fijian names, a statement of status (native, endemic, or introduced), and brief sections on distribution, description, habitat, reproduction, behavior, threats (cats and mongoose as well as deforestation), and similar species. All accounts are accompanied by a point locality map of Fiji and one or more color photos (as well as line drawings of subdigital features for all geckos and all but one skink). The book closes with a glossary with 89 entries, a reference list, an index to species and genera, and a short appendix on finding, collecting, transporting, killing, and preserving specimens.

For amateur naturalists or visitors to Fiji, this concise book will certainly be an adequate guide to the fauna, although its binding does not appear to be up to the rigors of the field. The photographs are mostly of good quality, though sometimes too small, and the maps and habitat descriptions will help to narrow down the species likely to occur in particular areas. In some cases, however, use of the guide is likely to require having the specimen in hand, as some geckos (e.g., *Hemidactylus frenatus* and *H. garnotii*) and skinks (e.g., *Emoia cyanura* and *E. impar*) may require detailed observation of scalation and/or color pattern to permit unambiguous identification by the uninitiated.

Despite its general utility, herpetologists may be disappointed in some aspects of the book. Although typographical errors are few and inconsequential, there are enough misstatements or inaccuracies to be irksome. These include a statement that implies that salamanders and caecilians all have aquatic larvae and the contention that all reptiles posses a three-chambered heart. In the species accounts original tail length is reported as less than SVL in *Hemidactylus frenatus* (it is typically 100–110% of SVL; Bauer and Sadlier 2000) and a maximum size of 3 m is reported for *Candoia bibroni* (the actual maximum is under 1.5 m; Harlow and Shine 1992). Names and terms are also problematic: *Hemidactylus garnotii* is consistently misspelled as *H. garnotti*, the names Crocodilia and Testudinae or Testudinata are used rather than Crocodylia and Testudines, and the terms parotid (or paratoid) and oviducal are employed rather than the correct parotoid (Tyler et al. 2001) and oviductal (Smith et al. 1989).

More central to the goals of the book are difficulties associated with distributional data. To begin with, the source of the localities plotted is unclear, except that some are derived from the records of the United States National Museum. At least some of the island records appear to be previously unpublished, but their basis is not mentioned. In some cases there are significant mismatches between the localities mapped and the distributional text. For example, *Platymantis vitianus* has been recorded from Koro and Kadavu, points not plotted on the map, while the islands of Beqa and Ovalau, which are shown with localities plotted, are not mentioned as among the areas harboring the species. At least some of these inconsistencies seem to have a common source. For example *Gehyra mutilata* has been mapped on Taveuni and *G. vorax* on Kadavu, but these islands are not included in the distributional statements of the respective accounts. These appear to represent

localities reported by Zug (1991) based on sight or photographic records, which have here been excluded from the distributional statements but mapped identically to localities represented by voucher specimens. Other problems include omissions in the extralimital ranges of widespread taxa: the Loyalty Islands have been omitted from the stated distributions of *G. vorax* and *Candoia bibroni*, *Hydrophis coggeri* has not been mentioned for New Caledonian waters (see Bauer and Sadlier 2000; Ineich and Laboute 2002), and the occurrence of *Brachylophus fasciatus* in the French territory of Wallis et Futuna (Etheridge 1981) has not been noted. A final criticism is that references are not cited in the text, making it difficult to track primary sources of interest. Many of these are included, however, in the list of 36 references provided at the end of the book. But while this bibliography includes the majority of important references for Fijian amphibians and reptiles, including several published locally in *Domodomo*, the journal of the Fiji Museum, at least a few important references have been omitted including Brown and Myers (1949), Brown (1991), Bauer and Henle (1994), and Shea (1995).

Regardless of any faults, the paucity of literature on the herpetofauna of the Southwest Pacific dictates that *A Field Guide to the Herpetofauna of Fiji* will be a useful addition to the libraries of herpetologists with an interest in the region. It will also be a great help to local naturalists and ecotourists for whom access to (or interest in) the primary literature is likely to be limited. Thus, the book will undoubtedly "stimulate interest, understanding and appreciation for" the amphibians and reptiles of Fiji, and thereby achieve the most important of its author's stated goals.

AARON M. BAUER
Department of Biology, Villanova University
800 Lancaster Avenue, Villanova, Pennsylvania 19085
e-mail: aaron.bauer@villanova.edu

The original 1995 German edition of this book on chameleons was favorably reviewed by Bauer (1997a). Since then, a second German edition has appeared (1999) and a third German edition is being published concurrently with this second English edition. The current version is more than 100 pages longer than the first edition, despite being more restricted in its content (the genera *Brookesia* and *Rhampholeon* are to be dealt with in a forthcoming companion volume). Like the original version, the book is divided into a "general" section dealing with chameleon systematics and biology, as well as chameleons and human culture and chameleon keeping. This is followed by a longer "special" section with detailed species accounts covering 51 species (including eleven taxa added since the previous edition) of *Chamaeleo*, *Bradypodion*, *Furcifer*, and *Calumma*. The general section is aimed at a non-specialist audience, but provides much information and is fully referenced. Major topics include morphology, tongue projection, color change, reproduction, and behavior. The section on care in captivity emphasizes that different species require quite different conditions and includes sections on housing, feeding, health, and husbandry. Species accounts in the special section provide Latin and vernacular names in English, German, and French, as well as information on identification (characteristics), systematics and zoogeography (subspecies and distribution), and habitat. Each account closes with details of biology and captive care interwoven and a list of suggested literature sources. Accounts range from one to seven pages, reflecting the varying amount of information known about the species. All species treated are illustrated by a minimum of two color photos and many have eight or more. In many cases both sexes, as well as hatchlings or juveniles, are depicted, as are different color patterns.

In my previous review (Bauer 1997a) I complained about the quality of illustrations. In contrast, they are a real strength of the current edition, having expanded from 250 color photos to more than 450 with notable improvement in both quality and size (although in some cases the additional images are gratuitous). In addition the photos appear with their respective accounts (vs. grouped

in plates in the first German edition) and even a subpar computer-generated distribution map in the earlier edition has been scrapped in favor of a more informative and attractive color replacement. In all, at least 90 species, including several as yet undescribed, are figured.

The book ends with a series of useful appendices. One is a table of living species summarizing habitat and vegetation type, reproductive mode, and size. The others are more taxonomically relevant: an up-to-date list of living and fossil forms of chameleons with author, type locality (unfortunately not verbatim), and distribution, a chronological list of names of chameleons as originally described, with comments on the status of each name, and a list of chameleon generic names (both intentional and erroneously applied). These appear to be comprehensive except for two obscure synonyms, too recently "rediscoved" to be included (Böhme and Das 2002; Bauer and Petit 2004). A bibliography of nearly 2000 references, about twice the size of that in the original, provides a superb entree into the ever-expanding chameleon literature. The glossary of the original is again present, and again there is no index, except to figures.

I found relatively few minor misstatements or inconsistencies in the text (e.g., the pre-1994 names for South African provinces are still employed; Karachi—rather than Islamabad—is referred to as the capital of Pakistan). My main disappointment in this otherwise highly useful book is that it lacks a real review of chameleon phylogenetics. While this may be beyond the scope of a book mostly aimed at chameleon enthusiasts rather than professional herpetologists, at least a brief summary would have been appreciated. It also would have had practical relevance for the organization and application of names in the book. For example, both morphological (Bauer 1997b) and molecular data (Townsend and Larson 2002) have demonstrated that East African *Bradypodion* are not members of same clade as the southern African forms to which that name is correctly applied.

Although the primary audience for this book is likely to be the many keepers and breeders of chameleons, others will also find it a valuable resource. My copies of the earlier editions have been well-used and I suspect that I will turn to this new version in the future for its photos and bibliography in particular. No one has yet written the ultimate chameleon book, but with this volume Petr Neças and Edition Chimaira have produced an attractive and authoritative work that will be a valuable addition to the libraries of both amateur and professional herpetologists.

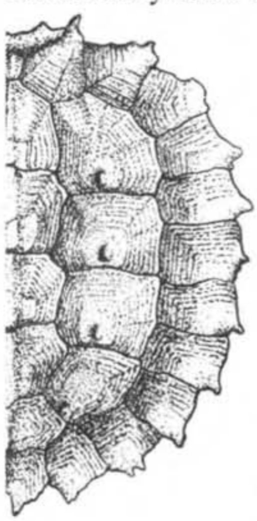
A New Facsimile Reprint from the Society for the Study of Amphibians and Reptiles

LES TORTUES DE L'INDOCHINE

by René Leon Bourret

Bourret's *Les Tortues de l'Indochine*, published in Vietnam in 1941, was the first complete and detailed monograph to deal with the turtles and tortoises of Southeast Asia. Although focused on French Indochina (Vietnam, Laos, Cambodia), the book treats the chelonian fauna of a larger area, extending from northeastern India to southern China to the Malay Peninsula. The book was based on work conducted during Bourret's decades of study in Vietnam and forms part of a series of his major publications on the herpetofauna of the region. More than 60 years after its original publication, *Les Tortues* remains an essential work in chelonian systematics and Southeast Asian herpetology. Published at the outset of more than 30 years of turmoil in the region, the book has long been a rarity and is among the most desirable of 20th century turtle books.

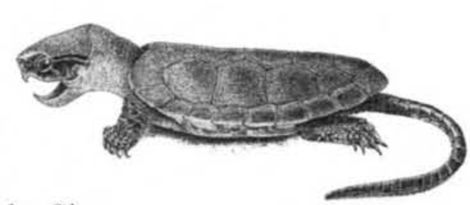


Detailed accounts are provided for 44 species of chelonians in 25 genera. Because of taxonomic changes these correspond to 56 currently recognized species in 34 genera. Species accounts are illustrated by more than 100 drawings and photos of whole turtles, skulls, carapaces and plastra. Six species are illustrated in color. In addition, the book provides a series of keys based on both skeletal and external characters, as well as chapters dealing with turtle morphology, the history of chelonian research in Indochina, and the faunal composition of the Indochinese region. An appendix on marine turtles and the turtle fishery in the Gulf of Siam by F. Le Poulain rounds out the volume, which also includes a 26-page bibliography.

Les Tortues de l'Indochine, originally published in the Notes de l'Institut Océanographique de l'Indochine, has long been out of print. With the publication of the new SSAR facsimile edition this classic book is again available to herpetologists with interests in turtles and tortoises or in the herpetofauna of Southeast Asia. The original French text is reproduced and a new English introduction by Indraneil Das of the Universiti Malaysia Sarawak places *Les Tortues de l'Indochine* in its historical context and provides an annotated correspondence between Bourret's nomenclature and that in current usage.

SPECIFICATIONS: 264 pages, 7 x 10 inches, 48 black and white and 6 color plates, clothbound. ISBN 0–916984–64–8. To be published April 2005.

PRICES AND SHIPPING COSTS: Pre-publication cost to SSAR members US$55 (valid through 15 May 2005); Institutions, and non-members $65 • Shipping: USA address, add $4; non-USA $9.



SEND ORDERS TO: Breck Bartholomew, P.O. Box 58517, Salt Lake City, Utah 84158-0517, USA (*telephone and fax*: area code 1-801-562-2660; *e-mail*: ssar@herplit.com). Please make checks payable to "SSAR." Overseas orders must be paid in USA funds using a draft drawn on an American bank or by International Money Order. Orders may also be charged to MasterCard or VISA (Please provide the account number and card expiration date). SSAR membership information and a complete list of all Society publications can be obtained on request to Mr. Bartholomew or at www.ssarherps.org.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.html>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR Treasurer (Dr. Theodora Pinou; contact information below) or from the SSAR web page (http://www.ssarherps.org/pdf/Adrates.pdf).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Dr. Theodora Pinou, SSAR Treasurer, Western Connecticut State University, Department of Biological & Environmental Sciences, 181 White Street, Danbury, Connecticut 06810, USA. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below), regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

In Situ Prevention of Anuran Fertilization: A Simple Method for the Detection of Sperm Competition with Potential for Other Applications

A. HETTYEY
and
J. TÖRÖK
Behavioural Ecology Group, Department of Systematic Zoology and Ecology
Eötvös Loránd University, Pázmány Péter sétány 1/c
1117 Budapest, Hungary
e-mail (AH): hettyeya@freemail.hu

Sperm competition is recognized as an integral component of sexual selection, shaping life-history characteristics such as body size, morphology, physiology and behavior (Birkhead and Parker 1997). Sperm competition occurs when there is competition between the ejaculates of different males for the fertilization of a given set of ova (Parker 1970). Therefore sperm competition can be shown by detecting mixed paternity using molecular methods (Queller et al. 1993; Roberts et al. 1999), by direct observation of multiple male - single female copulations (Birkhead and Parker 1997; Jennions and Passmore 1993) and by comparing relative testis sizes and sperm traits among and within species based on sperm competition theory (Byrne et al. 2002; Harcourt et al. 1981). However, despite the relatively high number of proposed methods it remains difficult to assess sperm competition in external fertilizers, and our knowledge of the occurrence of sperm competition in externally fertilizing anuran taxa has remained scarce (Halliday 1998).

In the externally fertilizing anurans, the production of offspring often numbering in the hundreds or thousands may render molecular paternity analyses uneconomical. Similarly, comparative methods using testis sizes and sperm traits require large sample sizes (sometimes more than a hundred) of sacrificed animals (Jennions and Passmore 1993; Kusano et al. 1991). This method is also problematic because it does not provide direct evidence for sperm competition (Birkhead and Parker 1997). Behavioral observations (e.g., Fukuyama 1991; Kaminsky 1997; Kusano et al. 1991) also share the latter burden.

In order to demonstrate the occurrence of sperm competition in a rhacophorid frog, Jennions and Passmore (1993) proposed a simple method for the documentation of sperm release by peripheral males in multiple male amplexes. Before oviposition, they placed the amplexed male's lower body in a plastic bag (20 x 20 cm) and let the pair spawn in the presence of peripheral males. After embryonic development they counted hatching larvae and unfertilized eggs. In control treatments, where peripheral males were excluded, fertilization success was zero, whereas in the experimental trial, where peripheral males were present, hatching success was nearly 37%. They concluded that plastic bags act as effective condoms, and that peripheral males sired the tadpoles in experimental treatments. Their method, however, has some substantial weaknesses: Jennions and Passmore only performed

two controls and one experimental trial, thus they did not test their method thoroughly for repeatability. They also noted that the plastic bag might have affected the rate at which peripheral males came into close contact with the female's cloaca, possibly reducing fertilization success. Furthermore, it is inevitable that the primary male would be hampered with its lower body completely wrapped in a 20 x 20 cm plastic bag, presumably leading to altered behavior and a strongly decreased ability to keep peripheral males away from the female.

We propose here an alternative technique that overcomes these problems by using condoms instead of plastic bags. Condoms were washed with soap before use to remove the lubricating gel, which could adversely affect study animals. After rinsing soap residue off with water, two holes were cut opposing each other in the condom. The size of the hole depended on the thickness of the proximal end of thighs of males, as it must prevent sperm leakage but not compress the blood vessels of the legs. Handling and fixing of the condom was easier when the condom was not unrolled completely. Once these preparations were completed, one person held the condom and stretched it open so that the holes for the legs became wide and the other person could easily pull the hind legs of the male one by one through the holes and smooth out the condom on the abdomen. The condom was fastened with two 20 cm long pieces of yarn bound as slings around the abdomen covered by the condom, one just under the fore-limbs and another above the hind-limbs and the cloaca (Fig. 1). The slings were tightened enough to prevent the condom from slipping down the body.

Amplexed pairs of *Bufo bufo* were hand-collected from a breeding-site in the Pilis Mountains (47°42'N, 19°01'E) 25 km N of Budapest, Hungary on five occasions in mid-April 2002. Pairs were transported in covered plastic boxes to the Ecology Laboratory at Eötvös Loránd University, Budapest, where trials were conducted within 24 hours of capture. Two inflatable plastic wading pools (120 cm x 120 cm, 60 cm deep) filled to a depth of 25 cm with aged tapwater were used as artificial egg-deposition sites.

We ran one control (no condom) and one experimental trial (with condom) at a time. Treatments were assigned randomly to wading pools. A total of five replicates were performed for each treatment. Pools were washed thoroughly with aged tapwater between successive trials. Treatments were terminated following egg deposition, which occurred within 16 hours in all cases. Animals were then removed and returned to the site of their collection, and egg strings were placed into uncovered boxes (55 cm x 35 cm, 30 cm deep) filled to a depth of 3 cm with aged tapwater. Eggs were stored for approximately three days at room temperature, so that embryonic development advanced to Gosner stage 18 (Gosner 1960). After this time fertilized and unfertilized eggs could be readily distinguished. In clutches taken from experimental trials we counted all eggs, but estimated egg number in the controls only to the nearest 100, as control treatments were only applied to test whether the experimental design grossly modified reproductive behavior and/or fertilization success. Embryos were reared until hatching and were then released at the site of their parents' collection. Experimental trials were video recorded to survey if the condom affected the behavior of the amplexed pair and whether it remained set in its place.

Bufo bufo females (N = 5) deposited on average 5305 eggs in

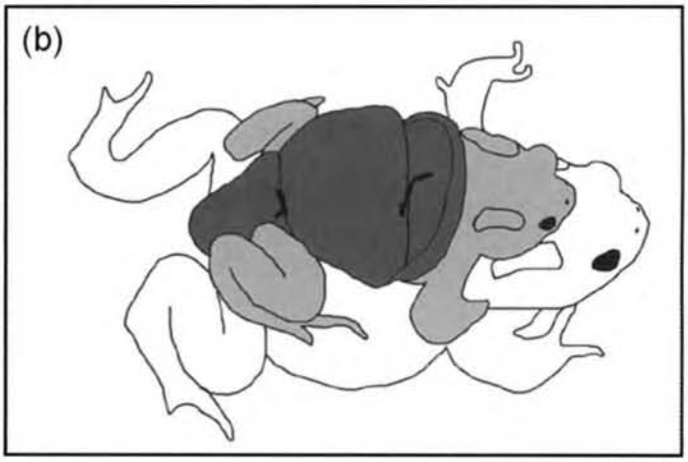

FIG. 1. (a) Photograph of an amplexed *Bufo bufo* male equipped with condom. (b) Diagrammatic interpretation of photograph in (a): Female: white, male: light grey, condom: dark grey.

experimental trials (N = 5; SD = 1121) and 5360 eggs in control treatments (N = 5; SD = 1064). We found no difference in number of eggs deposited between experimental trials and control treatments (Student *t*-test, $t_8 = 0.08$; $P = 0.938$). Average fertilization success was 0.303% (SD = 0.293) in experimental trials and 93.2% (SD = 8.55) in control treatments, and this difference was strongly significant (Mann-Whitney $U = 0.00$; $P<0.01$). In two cases the pair in the experimental trial started egg laying first, in three cases it was the pair in the control. There was no observable change in the position of condoms in any of our experimental replicates. Video records confirmed that the males did not try to remove the condoms, that the condoms remained in their position and that the males remained in amplexus until egg deposition was complete. After treatments, condoms contained an opaque fluid that we checked for spermatozoa under a light microscope, at 800x magnification. We found actively swimming spermatozoa in high numbers in the condoms of all experimental replicates.

Birkhead and Parker (1997) suggested two ways to detect sperm competition in internally fertilizing species: 1) by direct observation of multiple male mating assemblages, and 2) by detecting mixed paternity. However, it is important to note that both methods have limitations. In the first, copulation does not always result in insemination. In the second, it is possible that secondary males do not sire any progeny. Birkhead and Parker (1997) con-

cluded the combined use of both methods is desirable despite the difficulties in carrying out such studies. The same requirements should also apply to externally fertilizing species with the modification that, instead of multiple copulations, sperm release by multiple males targeting the same set of eggs must be detected. With our method it is possible to satisfy both of Birkhead and Parker's (1997) requirements without the use of molecular markers. If the focal male of a pair is equipped with a condom and the resulting clutch contains a high ratio of fertilized eggs, sperm competition can be assumed to occur under natural conditions as sperm from males other than the focal male must have achieved those fertilizations.

The testing of our method showed the following: 1) Fertilization success was negligible in all experimental trials, indicating that our method is effective in the retention of sperm of the amplexed male; 2) Among experimental trials we found low variance in fertilization success, showing our method to be highly repeatable; 3) Low fertilization success was due solely to the inhibition of fertilization by condoms, as average fertilization success in control treatments was comparable to that found in natural populations (A. Hettyey, pers. obs.) 4) Video records showed that the condoms applied as described stayed in position throughout the trials, allowing males to use their hind-legs without any difficulty. The condoms fitted *Bufo bufo* males tightly, clinging onto the males' abdomen and clearly not hanging over the females' cloaca. Thus they would not have prevented the sperm of other males from fertilizing emerging eggs; 5) High numbers of live spermatozoa were found in the condoms after termination of experimental trials, again documenting the efficacy of condoms in retaining the ejaculate. We note, however, that condoms appropriate for use in *Bufo bufo* and other large and medium-sized species may not be applicable for small frogs and toads. In this case pharmaceutical finger cots can be used instead of condoms (A. Hettyey, unpubl. data).

The fact that our method enabled the collection of ejaculates suggests other applications of this technique. For instance, artificial fertilization is a widely used method in a variety of studies (e.g., Berger and Rybacki 1992; Rakitin et al. 1999; Semlitsch 1994). In anurans the traditional method of obtaining sperm for artificial fertilization is to sacrifice and dissect the males, squash their testes, and then prepare sperm-suspensions (Berger et al. 1994). Such sacrifice may bring up ethical and conservation problems, possibly constraining the researcher's ability to obtain sperm from some populations or species. Gutleb et al. (2001) have shown that water that came into intensive contact with latex gloves can damage amphibian larvae. However, in our experiments, animals did not seem to be harmed by the condoms and the condoms contained live, actively swimming spermatozoa after trials. Consequently, we conclude that our technique allows the collection of sperm without killing or damaging males and allows the use of ejaculated sperm (which is superior in many aspects to sperm from dissected testes (Wilson et al. 1998). Another possible application is the testing of sperm competition theory suggesting differences among and within males in quality and quantity of sperm spent on distinct ejaculates (for a review, see Parker 1998). Predictions offered by theory have not been tested in anurans so far, probably due to the lack of an appropriate method of ejaculate sampling. As our technique retains almost the entire ejaculate, it offers the possibility to examine actual ejaculates and to compare them among or within individuals. Potential applications of our method are the detection of mating preferences at the level of ejaculate expenditure and toward male quality estimation based on sperm characteristics. Although this might be accomplished using the traditional dissection approach, our method collects only ejaculated sperm and avoids collecting samples contaminated with cells not directly involved with fertilization.

Acknowledgments.—We thank the Duna-Ipoly Nemzeti Park for permission to conduct experiments with frogs captured in ponds in the Pilis Mountains and the Pilisi Parkerdő Rt. for allowing us to use their forestry roads. The work was facilitated by access to equipment and space of the Department of Systematic Zoology and Ecology, Eötvös Loránd University, provided by Klára Dózsa-Farkas. We thank M. J. Angilletta, J. V. Buskirk, T. W. J. Garner, P. B. Pearman and J. D. Roberts for comments leading to improvements of the manuscript.

The size and distribution of local marine turtle populations is critical for managers who need to know where and when the turtles congregate, what resources attract turtles to a given location, and how both the turtles and those requisite resources can be managed and protected. But obtaining this information is often difficult. Home ranges may be large, water clarity can be limited, and the turtles may avoid observers by fleeing or hiding before they can be detected.

The Palm Beach County, Florida (USA) Department of Environmental Resource Management has been aware that juvenile Green Turtles (*Chelonia mydas*) often were observed by local swimmers and divers near shallow water (1–5 m deep) reefs (Fig. 1). These reefs are long (up to 0.5 km), narrow (≤ 12 m wide), hard-bottom formations that parallel the shore along the Atlantic coast of southeastern Florida. In parts, the hardbottom is colonized by living worm reef, structures formed by the secretions of a colonial sabellariid polychaete (*Phragmatopoma lapidosa*). Throughout these reefs, sponges, soft and hard corals, and algae adhere to the hardbottom surface. Turtles feed on the macro-algae and seek shelter under ledges and within reef crevasses when inactive (especially at night; Wershoven and Wershoven 1988). Because the reefs provide food and shelter, they may constitute an important "developmental" (age-specific, temporarily utilized) habitat (Musick and Limpus 1997) for the turtles.

The reefs are popular boating and snorkeling sites. For that reason, we suspected that in-water observers towed behind a slowly moving, small boat would be an effective census method because the animals should be acclimated to both boat traffic and swimmers. This surveying method, colloquially referred to as "shark fishing" (derived from the towing of large "baits" [observers] through the water) is used in Hawaii by trap and spear fishers to locate prey. To our knowledge, no published studies have reported the use of this technique for estimating turtle abundance. We estimated the density of turtles in the shallowest of these discontinuous reef formations, and determined whether turtles were more abundant over the reefs than over the sandy areas separating reefs. Our results indicate that the method works in clear water and might be useful at other subtropical and tropical reef locations worldwide. We also describe its limitations.

Methods.—In-water surveys were performed by two observers wearing a mask and snorkel, each holding one end of a 5-m long tagline. The other end of each line was attached to each side of a slowly (2–3 nautical miles/h) moving small (~ 6 m long) powerboat, traveling directly over the reef axis parallel to shore. Observers visually scanned the bottom directly below and to the left (port observer) or right (starboard observer), as far as water clarity permitted (typically, 8–12 m to each side). When a turtle was seen, the boat operator was informed and stopped the boat to record the time, water depth, and the turtle's geographic position (using a GPS and depth sounder).

We surveyed the county's three primary shallow reefs (north, south, and middle reef), as well as three sand bottom areas at similar depth between the reefs (Fig. 1). The total length of the reef (12.1 km) and sand (10.0 km) surveys accounted for ca. 30% of the county's shoreline. Surveys were carried out in July–August 2001 (over 9 days), and in July–September 2002 (over 5 days).

The short north and south reefs were surveyed in a single day; the longer middle reef required several transects done over a 2–4 day survey period, with each sequential transect beginning where the previous transect ended. Longitude and latitude were noted at the start and end of each transect, as well as at five min intervals during each survey so that both transect paths and turtle sightings could be accurately depicted on nearshore maps. Surveys were usually made between 0800 and 1200 h to avoid afternoon thunderstorms.

Results.—We observed 62 turtles over the reefs during the 2001 survey, and 79 turtles during the 2002 survey; none was seen over open sand (2001 survey). Turtles either were resting on the bottom, swimming over the reef, or feeding (apparently, on benthic macro-algae). As we passed them, most turtles within 5 m swam away slowly to one or the other side of the boat's path. Turtles observed at greater distance ignored us.

During the 2001 survey, 68% (42 of 62) of the turtles were separated by short distances (≤ 40 m) from one another (Fig. 2). This pattern did not change during the 2002 survey.

Discussion.—Our shore-parallel surveys assume that all of the turtles can be sighted because the animals confine their movements to a certain (in this case, elongated reef) area (Gerrodette and Taylor 1999). Support for this assumption is provided by studies in progress. One of us (CM) recently attached sonic tags to six turtles from the middle reef; each has confined its movements entirely to a discrete home range located directly over the reef. These results provide further support for the hypothesis that juvenile Green Turtles establish home ranges over reef substrates

(Balazs et al. 1987; Brill et al. 1995, for Hawaiian turtles; Guseman and Ehrhart 1990; Wershoven and Wershoven 1988, for Florida turtles; Seminoff et al., *in press*, for Baja California turtles).

"Shark Fishing" as a survey technique has several advantages. It is (i) technically simple, (ii) time-efficient (5–9 d required to survey 12 km of reef), (iii) requires no permit (and lengthy review process), and (iv) does not appear to disturb the turtles. But the method also has limitations. Good visibility (≥ 7 m) is required. Because turtles are not individually identified they may be counted more than once, especially when reef tracts are long and require several days to survey. The method assumes that the population is static (no immigration or emigration) during the survey period. At our site that assumption is probably correct during the summer when the turtles occupy fixed home ranges, but not during the spring and fall when juvenile Green Turtles are known to seasonally migrate (Bresette et al. 1998). Because size is estimated (rather than precisely measured), information on size class distribution is limited.

In Palm Beach County and elsewhere in South Florida, similar reef formations are also located in deeper water, and Green Turtles are routinely observed there (J. Abernathy, SCUBA adventures, pers. comm.; Ben Harkanson, Palm Beach County Reef Research Team, pers. comm.). Thus, our survey is an incomplete assessment of reef-dwelling population density; counts made by divers (using SCUBA) over the deep reefs are also required.

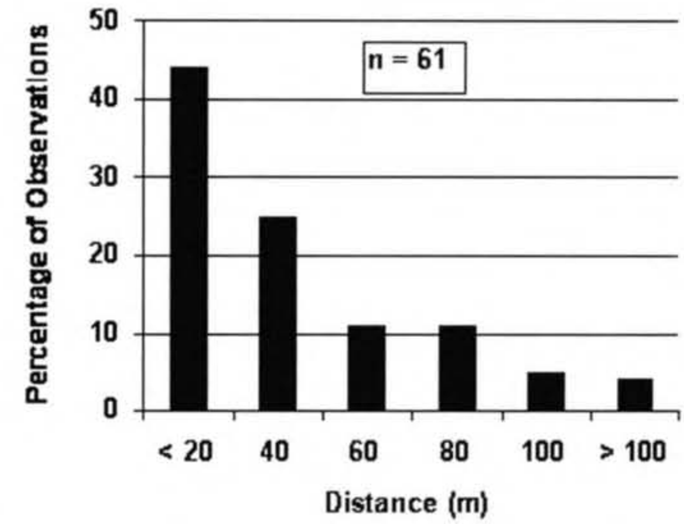

FIG. 2. Distribution of distances between turtles observed over the reef, 2001 field season. N = number of intervals.

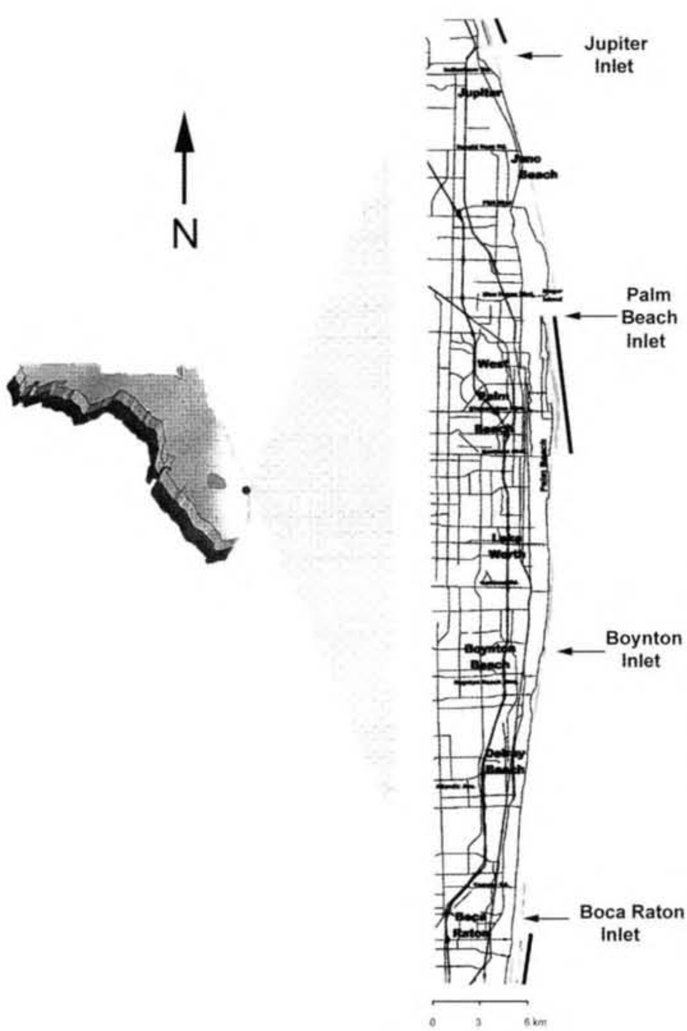

FIG. 1. Coastal shoreline of Palm Beach County, showing the major inlets and the approximate location of the north, middle, and south inshore reefs (dotted lines).

At other developmental habitats in Florida, different methods are used. One procedure is to count the number of turtles seen surfacing to breathe as a boat and its operator travel along a transect line. This method is useful where water clarity is limited, but is compromised when the water surface is disturbed (by waves or rain) or the turtles occur at low densities (reducing the probability of detection; Gerrodette and Taylor 1999). We observed only five turtles breathing at the surface during our 2001 survey. Additionally, surface counts must be corrected for turtles that are submerged at the time of the survey and, because individuals are not identified, some turtles may be counted more than once. Thus, headcount surveys (including those obtained by shark fishing) can be used to estimate densities of turtles, but not their absolute population sizes.

Another procedure, useful in shallow lagoons and tidal channels where visibility is limited, involves the use of tangle nets (Ehrhart and Ogren 1999). Captured turtles are marked using flipper tags. Their recapture probabilities are determined over repeated net sets. The procedure is labor intensive, but it is effective for estimating relative abundance if continued over several months or years. Population estimates based upon mark and recapture techniques, however, also carry assumptions (e.g., there are no deaths, immigration and emigration rates are constant, tags are not lost, tagging does not affect recapture probability, etc.). Nonetheless, this is the preferred method at some habitats, such as the Indian River Lagoon (Ehrhart and Ogren 1999; Mendonça 1983; Mendonça and Ehrhart 1982). Netting is difficult at oceanic nearshore reefs where tidal flow and surge can cause the net to be caught on, and damaged by, the reef. However, it has been successfully employed to estimate Green Turtle relative abundance and seasonal occupancy at habitats where water clarity precludes direct observation (Guseman and Ehrhart 1990).

In-water "Shark Fishing" surveys are an effective procedure for estimating Green Turtle population densities in clear water habitats. These observations can be enhanced by using sonic and/or satellite telemetry to pinpoint daily and seasonal movements. This information is essential for specifying home range characteristics, and for insights into both ecological requirements as well as for effective management and protection strategies (Mendonça 1983; Musick and Limpus 1997). Our two-year study, for example, provided important baseline information to Palm Beach County personnel. A beach restoration project is planned for the coastline adjacent to the middle reef where the Green Turtles are most concentrated. Pumping sand to the beach can have consequences that seriously compromise the integrity of near-shore reef habitats (Crain et al. 1995). Our data will make it possible for the County to assess these effects on Green Turtles, which are currently listed as endangered under the authority of the Endangered Species Act (National Marine Fisheries Service and U.S. Fish and Wildlife Service 2002).

Acknowledgments.— Funding for this study was provided by the National Save-The-Sea-Turtle Foundation of Fort Lauderdale, Florida. We thank Robert Ernest, Jeanette Wyneken, and an anonymous referee for their comments.

As human encroachment into upland areas inhabited by Gopher Tortoises (*Gopherus polyphemus*) has accelerated, the need to protect tortoises during construction activities has increased. Commonly, tortoises at construction sites are captured and relocated or temporarily displaced until construction is complete (Wester 1995). Various methods of capture are employed; including opportunistic capture by hand, live trapping, and excavation. Capturing tortoises by hand depends on finding them out of their burrows. If the capture is made while the tortoise is within the burrow, it can be injured in its retrieval. Live trapping often takes many days to accomplish. Increasingly, excavation has become the method of choice for the capture and translocation of Gopher Tortoises. Excavation involves digging tortoises out of their burrows either with a hand shovel or by mechanical means. Although we do not advocate one method of capture over another, here we report on an effective method for mechanical excavation of Gopher Tortoises.

Currently, no uniformly recognized standards exist for mechanical excavation of Gopher Tortoises or their commensals. We have used the technique described here since 1994 to excavate Gopher Tortoises in Mississippi, Alabama, and Florida. The method is not complicated, but involves expensive equipment and skilled personnel. We present our findings so that the process of mechanical excavation can be standardized and made safer for tortoises, burrow commensals, and personnel involved in the procedure.

The equipment necessary to successfully excavate a tortoise burrow with the methodology described here is listed in Table 1.

Biological Considerations.—The presence and location of tortoises and commensals should be determined before digging to

help ensure capture without injury. A burrow camera can be used to survey the length of the burrow for occupancy. The usefulness of these devices is highly dependent on equipment design, field conditions, and the skill of the user. If burrow occupants can be seen with a camera, it may be possible to determine the species present, number of individuals, and location within the burrow. Knowing the relative position of the burrow occupants will help avoid injury during excavation. Knowing the species present also may influence the process (e.g., some vertebrate species may leave voluntarily overnight once disturbed).

Most mammal and bird species tend to leave tortoise burrows voluntarily given the opportunity. We recommend that commensals that do not leave the burrow voluntarily be translocated along with tortoises. Commensals may include vertebrate as well as invertebrate species (Franz 1986; Jackson and Milstrey 1989; Speake 1981; Young and Goff 1939). Certain species, such as Gopher Frogs (*Rana capito*), over-wintering snakes, and Florida Mice (*Peromyscus floridana*) may require relocation via excavation.

It is important to keep in mind certain other circumstances when determining burrow occupancy. Multiple occupants in a burrow, although not common, may occur at any time of the year, especially during the breeding season, April to June. In addition, flooded burrows are not necessarily unoccupied. We excavated two tortoises from the same burrow after a burrow camera revealed the burrow to be flooded and no tortoises were observed above the water line. Even though burrow cameras can be quite useful, they cannot be relied upon to determine if a burrow is unoccupied. All burrows should be considered occupied until proven otherwise.

Preparing the Burrow for Excavation.—Prior to disturbing the burrow, measurements, photos, and other descriptive data should be recorded. The burrow apron then should be thoroughly excavated by hand to find and protect any unhatched reptile eggs.

Gopher Tortoise eggs, which are hard-shelled and brittle, will generally be found 10–26 cm deep (Diemer and Moore 1994; Hallinan 1923; Landers et al. 1980) between April and September (Brode 1959; Mount 1975). Because the nesting season for Gopher Tortoises varies so widely across the range, we recommend excavation of the apron at any time of the year. Eggs should be marked on top with a pen or pencil; gently transferred to an insulated, padded container without altering orientation; immediately translocated to an area with similar ground quality and canopy cover, such as another burrow apron; protected from ground traffic; and buried at the same depth as found. To deter predators, wire fencing or other protection of sufficient mesh size to allow hatchlings to escape should be placed over the new nest site (Butler and Sowell 1996; Landers et al. 1980; Wilson 1991).

Plastic conduit tubing, such as 1.9 cm (3/4 inch) outside diameter PEX tubing, with graduation markings along the length, and with an attached blunt end fitting should be inserted to the end of the burrow and left in place. An empty, single-serving plastic soda bottle taped to the tubing works well for this purpose. This serves as a guide to determine the location of the burrow channel during excavation. The blunt end allows the tube to be inserted without embedding itself in the wall of the burrow. Mechanical excavation can begin once the plastic conduit is fully inserted into the burrow.

Excavation.—Utilization of heavy equipment is inherently dangerous. Skilled, properly licensed backhoe operators and trained biologists should be involved. Local and federal authorities governing the disposition of tortoises or their commensals should also be involved in the process. This includes procurement of proper permits and licenses. In addition, guidelines for safe operation of heavy equipment and excavating procedures as put forth by the Occupational Safety and Health Administration (OSHA) should be followed.

The backhoe is positioned ca. 4–6 m (depending on the length of the excavating arm) behind the burrow entrance (opposite the apron) and over the burrow tunnel, with the excavating bucket extending toward the burrow entrance. One or more ground personnel direct the backhoe operator during the entire excavating process. Burrow tunnel direction can be communicated to the operator by placing a shovel handle in the burrow showing the long axis of the tunnel. The skill of the backhoe operator is essential to safe excavation. The flat leading edge of the bucket is used to scrape away earth over the top of the burrow in a horizontal pulling or "sweeping" motion. It is important that the bucket be pulled horizontally toward the backhoe and not allowed to dip or arc into the tunnel. The depth of each pass of the bucket into the ground should increase only by centimeters with each pass. Done properly, the backhoe bucket should never enter the lumen of the tunnel. Ground personnel should remove the layer of earth comprising the top of the burrow with hand tools and determine the direction of the tunnel. Often, the tunnel will change direction and the backhoe must be repositioned to orient the pull of the bucket parallel to the direction of the tunnel. The guide tube should be checked frequently for proper insertion and advanced as far toward the end

TABLE 1. Necessary equipment for Gopher Tortoise burrow excavation.

Equipment	Approximate Cost (US $)
Backhoe Loader (416 or 420 Caterpillar or equivalent), equipped with 0.61-m wide bucket with a smooth cutting edge (i.e., no digging teeth)	$300/hr with operator
Closed-circuit burrow camera (see Kent et al. 1997)	$2,500
Portable drill	$100
Calipers	$41
Scales	$35-$75
35-mm Camera	$5-$500
Tape measure	$10
Pump sprayer (4-12 liter garden sprayer)	$20
10% Chlorine bleach (sodium hypochlorite)	$1
Shovel	$20
Flexible plastic conduit (6.7 m length, 1.9 cm diameter)	$5
19-Liter bucket	$10
Latex gloves	$17

of the burrow as possible. If a burrow camera could not initially visualize the entire length of the burrow, the camera should be used to recheck the burrow frequently during the excavation process. The burrow should be carefully excavated until the guide tube shows at least 1.25 m or more of burrow tunnel remaining. At this point, only shovel and hand excavation by ground personnel should be used to avoid injury to the occupant(s). Frequent visualization of the burrow and probing by hand should help avoid inadvertent injuries.

Tortoises and commensals should be removed when sufficiently exposed. Although burrow occupants normally retreat to the end of the burrow, we have not found a definitive means for determining if the end of the burrow has been reached. Tortoise burrows do not typically terminate in a "chamber" or other readily identifiable configuration. The following criteria, however, can be helpful in determining when a burrow has been completely excavated:
1. Soil may be more compact at the end of the burrow;
2. There may be a change in soil color and/or texture;
3. There may be a buildup of tortoise fecal material;
4. Often there is a collection of invertebrates (e.g., camel crickets, *Ceuthophilus* spp.) and/or surface vegetation at the end of the burrow; and
5. The insertion length achieved by the burrow camera and guide tube should correlate with the actual burrow length.

The burrow terminus should be carefully and thoroughly examined for additional tunnel branches (uncommon), commensals, and tortoises. Hand excavation is complete when one is convinced the entire burrow has been excavated. The vertical depth of the excavated trench should be measured prior to backfilling to determine the depth of the burrow. Burrow depth should be recorded along with other relevant burrow data, such as height and width of burrow opening and length of burrow. For an average burrow, the entire excavation process usually can be completed in less than an hour.

All materials used in excavation, data collection, and relocation, including the backhoe bucket, should be disinfected after each excavation/relocation. We used a hand held pump sprayer containing a 10% solution of sodium hypochlorite in water (bleach) (Smith et. al. 1998). The disinfectant should be allowed to dry or rinsed from the equipment and not contact live animals.

Data Collection and Relocation.—Biological information may be gathered on tortoises and commensals prior to relocation. To prevent the potential spread of diseases, a clean pair of disposable latex gloves should be worn when handling each animal. We recommend marking (Cagle 1939) and photographing tortoises for future identification. All animals to be relocated should be placed in their own appropriate holding container, protected from sunlight, temperature and humidity extremes, and relocated as soon as possible.

Wester and Kolb (1997) and Thomas (2002) have shown evidence that Gopher Tortoises displaced from their burrows but not released beyond major barriers such as streams or wetlands tend to remain in the vicinity of their release. We have noted tortoises attempting to re-excavate their original burrows within hours after being displaced. It is therefore important to re-check areas where tortoises have been excavated in order to avoid re-colonization of the site.

Historical Success Rates.—The capture and relocation of Gopher Tortoises by any means can cause stress, and all methods have some risk of injury. Excavation of burrows by mechanical means is a fast and effective method of displacing tortoises from construction areas, and if done correctly, presents minimal risk to the animal. Wester (1995) utilized a variety of methods to displace Gopher Tortoises along a pipeline corridor. Of 1514 tortoises displaced using a method of mechanical excavation similar to that described here, 15 (0.99%) suffered relatively minor injuries and were subsequently released, nine died (0.59%) or were euthanized as a result of injuries, and nine burrows collapsed during excavation and could not be reopened. Occupancy was in doubt for some of the collapsed burrows, but assuming a single tortoise occupied each, total mortality was 1.19%. Of the nine confirmed mortalities, at least one tortoise ascended the burrow during excavation, resulting in the operator and ground crew being unaware of its location. In another case, the burrow ascended toward its end, leaving the occupant at a shallower depth than anticipated. Other possible causes of mortality may have resulted from either operator error (allowing the backhoe bucket to go too deep and therefore invade the burrow cavity) or ground crew error (not using hand excavation soon enough near the burrow terminus). The nine burrow channels lost during excavation resulted from inadvertent removal of the guide tube during excavation or inadequate placement of the tube (end of the tube did not reach the end of the burrow) prior to digging.

We have successfully displaced several hundred Gopher Tortoises using the technique described without injury/mortality to burrow occupants. Utilizing data from several relocation projects with which we have had personal experience, including Wester's (1995) study, we estimate that a mortality rate of less than 2% for mechanical excavation with experienced personnel can be expected.

A Technique for Sampling Lizards in Rocky Habitats

BRETT ALEXANDER GOODMAN

e-mail: G.Peterson@zoo.latrobe.edu.au

Many techniques exist for sampling a vast array of lizard species, including noosing poles, grab sticks, scoop buckets, sticky sticks, rubber bands, sticky traps, and habitat traps (Bauer and Sadlier 1992; Bertram and Cogger 1971; Brattstrom 1996; Downes and Porges 1998; Durtsche 1996; Simmons 1987; Whiting 1998; Witz 1996). However, many lizard species live in habitats where sampling is inherently difficult. In particular, open rocky areas make sampling lizard populations difficult. This may be because lizard species inhabiting open rocky habitats often exhibit behaviors (e.g., increased wariness and/or flight distance), morphologies (e.g., increased relative limb length), and performance abilities (Bauwens et al. 1995; Melville and Swain 2000; Vanhooydonck and Van Damme 2003) that can make their collection both time consuming and labor intensive. Collecting is further compounded by the large number of potential refugia that are typically available within rocky habitats, resulting in lizards usually being close to suitable cover (Ingram and Covacevich 1978).

In an attempt to sample several skink species from rocky habitats in eastern Australia we searched for published reports of techniques that could be extended to collecting saxicolous species. In our experience we found most species to be too wary for capture by noosing, grab sticks, or sticky sticks. In an effort to increase capture success we used sticky traps (Zoro Zoro® cockroach traps, Japan Food Corp., Sydney, N.S.W.) baited with *Tenebrio* larvae or adult crickets (*Acheta*). Although this technique was an improvement on the former methods, it was also labor intensive, time consuming, and relatively ineffective in rocky habitats. For example, capture rates were relatively low (0.76 animals/hr), even with two persons each operating two traps. An additional problem with the collection of lizards with sticky traps is that captured individuals would occasionally autotomize their tail while struggling to free themselves from the trap. Because we were specifically interested in the locomotor performance of individuals with complete tails, this technique rendered such individuals inappropriate for study (e.g., Garland and Losos 1994; Melville and Swain 2000). More importantly, because a number of the species we intended to investigate are classified as threatened or rare, we were also concerned about the possibility of mortality following capture using sticky traps (Vargas et al. 2000).

Here we describe a simple and effective method for the collection of actively foraging lizards occupying rocky habitats. This technique may also be used to provide estimates of abundances within these habitats. The technique is a pitfall-style trap consist-

TABLE. 1. Capture-success rates using this technique and two other collection methods for five species of rock-dwelling skinks from eastern Australia. Numbers in parentheses indicate the total number of hours that each technique was used.

TAXON	HABITAT TYPE	BAITED BUCKET TRAPS (captures/trap hr)	BAITED STICKY TRAPS (captures/trap hr)	HAND CAPTURE (captures/person hr)
Carlia scirtetis	Granite boulders	2.1 (18)	1.1 (25)	0.3 (21)
Cryptoblepharus litoralis	Rocky coastal zones	3.4 (22)	—	1.8 (32)
Eulamprus brachysoma	Rock outcrops, boulders	3.1 (11)	—	2.6 (13)
E. tympanum marniae	Basaltic flows	2.25 (89)	2.1 (83)	—
Lampropholis mirabilis	Small river boulders	3.8 (38)	2.4 (24)	1.9 (64)

ing of a bucket and a tray of live food (*Tenebrio* larvae, or adult crickets, *Acheta*, with their hind legs completely removed). A circular tray (10 x 2 cm) containing live prey is positioned centrally at the same level as the mouth of the bucket or pitfall container (Fig. 1). The trap is then positioned between adjacent rocks or placed in a suitably sized vertical crevice so that the mouth of the trap is level with the rocks. We used traps with a 30–40 cm depth and a 40–50 cm mouth diameter. For traps of this size the distance

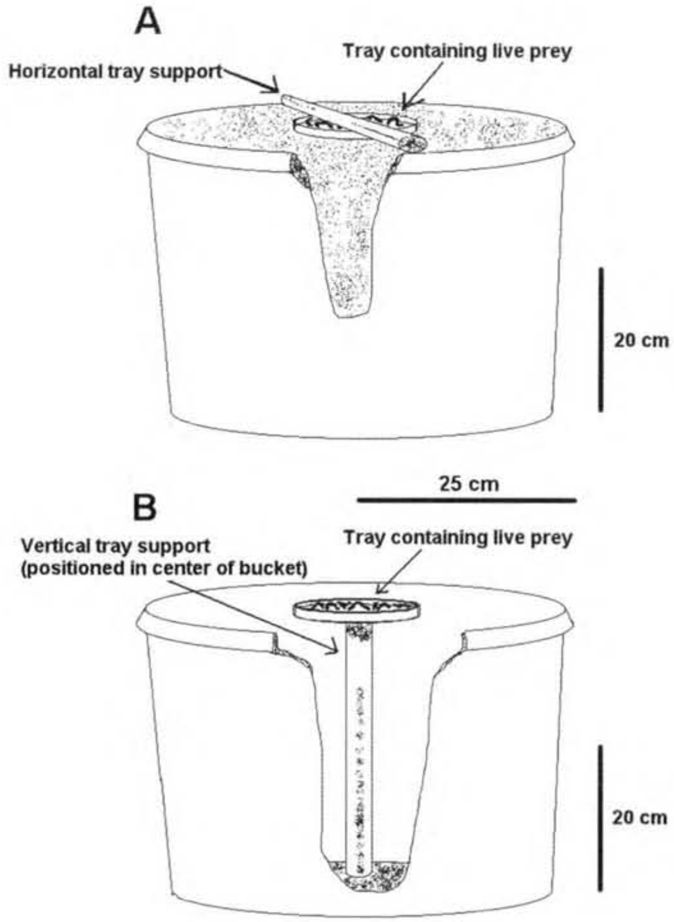

FIG. 1. Two variations of the baited-bucket trap that can be used to collect saxicolous lizards. The food tray can either be attached to the underside of a dowel spanning the mouth of the bucket (Fig. 1A), or mounted on top of a dowel that is fixed vertically to the center of the bucket (Fig. 1B).

from the edge of the prey tray to the edge of the bucket is 15–20 cm. As both trap diameter and depth may influence the size and composition of lizards species collected (Blomberg and Shine 1996), some experimentation with the design may be necessary. In addition, it may be necessary to secure traps into the desired position using supports or adhesive tape. Lizards are attracted to the trap by the movement of live food within the food tray.

Depending on the target species, we use one of two variations of our general trap design. The food tray can either be (1) attached to the underside of a dowel (1–2 cm diameter) that spans the mouth of the bucket (Fig. 1A), or (2) mounted on top of a vertical dowel that is fixed centrally to the base inside the bucket, such that the food tray is level with the mouth of the bucket (Fig. 1B). In the former design lizards are trapped in either of two ways: the lizard falls into the bucket while negotiating the dowel in an attempt to reach the food tray or, because the food tray is fixed to a dowel that is free to move, once on the tray the mass of the lizard causes the dowel and food tray to rotate causing the lizard to fall into the bucket. In the latter design, lizards fall into the bucket when they attempt to jump onto or from the food tray. We achieved the highest success (2.1–3.8 lizards/trap hr; depending on species) when we placed the trap in highly visible areas where live prey is more likely to be seen by active lizards from perching or basking sites. In hot environments, traps should be placed in shaded areas to avoid exposing the prey and captured animals to lethal temperatures, or refugia (e.g., leaf litter) could be placed in the buckets.

This collection technique allows a single researcher to set out and monitor a large number of traps. We have used this technique to collect small (SVL 30–100 mm; 1.3–25.0 g) saxicolous skinks that occur in several types of rocky habitat (Table 1). Overall, the baited bucket method provided marginal to substantial improvement in capture success for these lizards relative to other widely used collection techniques (Table 1). The technique is nondestructive and traps are quick to set-up and can be adapted to suit most types of rocky habitats. Further, because it is usually possible to position traps in a predetermined grid pattern within a rocky habitat, this technique may also be used to estimate lizard abundance. Although we have specified the use of this technique in rocky habitats, it might also be adaptable and effective in other habitats (e.g., arboreal rainforest species) where traditional collection techniques (e.g., pitfall trapping) are problematic.

Acknowledgments.—We thank A. Krockenberger, B. Malone, G. Bedford, R. Spencer, and two anonymous reviewers for their advice and

valuable comments on the article. We also thank R. Goodman and N. Peterson for technical advice on trap design and inspiration. The James Cook University Animal Care and Ethics Committee and La Trobe University Animal Ethics Committee approved the methods reported herein. Using Alpha Numeric Fluorescent Tags for Individual Identification of Amphibians

ARTHUR BUCHAN*
LIXING SUN

Drawbacks of various marking techniques for amphibians include potential harmful effects (toe-clipping; Brown 1997), mark longevity (toe-clipping, ink Panjet marking; Brown 1997), and cost (PIT tags; Brown 1997; Ireland et al. 2003). Recent techniques also can have varying negative effects such as length of handling time and invasiveness (e.g., pressurized fluorescent marking, coded wire tags, visible implant elastomers; see Nauwelaerts 2000 and Ralston Marold 2001 for review). Prefabricated biocompatible fluorescent tags (Soft VIAlpha Numeric Tags; Northwest Marine Technology Inc., Shaw Island, Washington) have been used extensively on fish (Frenette and Bryant 1996) but have not been tested on amphibians. Each tag is imprinted with a letter (A–Z) followed by a number (00–99) available with various color schemes (e.g., black letters on a red, orange, or yellow fluorescent background or the reverse). We conducted experiments to assess ease of application, readability, and tag retention on a variety of amphibians including 376 *Pseudacris regilla* (Fig. 1), and 1–3 *Taricha granulosa*, *Bufo boreas*, *Rana cascadae*, *Spea intermontana*, and *Rana luteiventris*.

Animals were tagged by making an incision using a sterile standard-size blood lancet and then inserting the tag using forceps or an injector (provided by Northwest Marine Technology). Individuals were physically restrained by hand with no anesthesia used during the procedure. Depending on the species, the tags were placed in the subcutaneous layer near the sartorius muscle on the ventral side (*Pseudacris, Rana, Spea, Bufo*), or into the tissue near the base of the tail on the dorsal side (*Taricha*). Post-injection sterilization consisted of cleaning forceps or injector with alcohol. Juveniles and smaller-sized amphibians such as *P. regilla* (size 15–45 mm) and *T. granulosa* (juvenile) were tagged with the smaller (1.0 x 2.5 mm) tags, and all other amphibians were tagged with the large (1.5 x 3.5 mm) tags. Retention rate, readability, and survival were monitored in the laboratory for 10–120 days depending on species studied. Further, a field test of tag efficacy was conducted with *P. regilla*.

Pseudacris regilla were tested on three occasions. First, tags were forceps-inserted in 10 individuals. The procedure was tedious requiring at least one minute per individual. Animals were monitored in the lab for 120 days; tag retention was 80% (2 tags slipped out the original incision), all tags could be read without ambiguity, and all animals survived. Second, 23 individuals were injector-tagged (using a blood lancet to make the incision) with tags of different color schemes (orange, red, and green tags with black lettering, and black tags with orange, red and green lettering) to compare readability. Injections took less than 15 sec per

FIG. 1. The alpha numeric tag for individual identification of amphibians.

animal, and animals were housed in the lab for 90 days; all tags were retained and readable without ambiguity. Survival of marked animals was 96%. One animal died because it became trapped between the cage and its lid. Third, 468 *P. regilla* were tagged and released into their natural habitats, of which 59 individuals were recaptured up to 210 days after tagging, with no apparent inflammation or swelling of insertion area, or deterioration of tags.

One *T. granulosa* was injector-tagged into tissue. The procedure took about 30 sec, the animal was housed for 60 days, during which time the tag was retained and was readable without ambiguity. Similarly, *B. boreas* (N = 1), *R. cascadae* (N = 1), *R. luteiventris* (N = 1), and *S. intermontana* (N = 3) were injector-tagged. The procedure took less than 30 sec, individuals were housed for 10 days, during which time all survived and retained their tags which were readable without ambiguity.

We found VIAlpha tags were efficiently applied when the tag injector was used in combination with a blood lancet. Survivability of animals and retention of tags was high. Further, tags were readable with no deterioration after 210 days. Tags cost approximately US $1.00 per tag, and the injector is approximately US $120.00. This appears to be an effective and low cost method for individually marking and identifying amphibians.

An Improved Method for Karyotyping Anuran Chromosomes

LAURA GUDERYAHN
e-mail: laura-guderyahn@augustana.edu

STEPHEN B. HAGER
e-mail: bihager@augustana.edu

and
LORI SCOTT
e-mail: biscott@augustana.edu

Department of Biology, Augustana College
Rock Island, Illinois 61201-2296, USA

Karyotyping is an effective and simple tool for analyzing basic genetic characteristics of organisms. This method is especially useful when assessing the presence in a given area of the morphologically indistinguishable species of the Gray Treefrog complex, *Hyla chrysoscelis* and *H. versicolor* (Wasserman 1970), found in the eastern United States because these species can be identified by chromosome number. Here we elaborate and improve upon previously published methods (Bogart 1967; Kligerman and Bloom 1977) for the extraction and acquisition of chromosome spreads for anuran DNA. Our method focuses on the attainment of spreads where the chromosomes are spaced relatively far apart so that each chromosome can be identified and studied. We found that karyotyping methods published by Bogart (1967) and Kligerman and Bloom (1977) resulted in mostly layered chromosomes, which made individual recognition and quantification difficult. Moreover, these other methods have either focused on fish as the model system for karyotyping or, if they are anuran specific, are not described in sufficient detail, which made replication in the lab difficult.

We used Cope's Gray Treefrog, *Hyla chrysoscelis*, as the model system for this technique. In July and August 2002 twenty individuals (12 larvae and 8 adults) were captured from Green Wing Environmental Laboratory, a biological field station located in north-central Illinois. All individuals were transported alive to the laboratory where karyotyping methods were completed. After each individual was sacrificed and the necessary tissue extracted for karyotyping, the rest of the body was immediately fixed in 10% neutral buffered formalin, and each is currently stored in 70% EtOH in the Vertebrate Zoology Collection at Augustana College.

Procedure.—Tadpoles in late larval stages, i.e., late 30s or early 40s based on Gosner (1960), or adult frogs can be used for this procedure. If using tadpoles, allow them to swim in 0.01% colchi-

cine solution for 12–24 h (Kligerman and Bloom 1977). Adult frogs, on the other hand, will need to be injected with a small amount of colchicine (1 mg/ml deionized water) using a 23-gauge needle (1.9 cm in length). To ensure circulation throughout the torso the colchicine solution should be injected through the skin of the dorsum and into the abdomen at a depth of ca. 3 mm. A frog 5 cm in length, such as Gray Treefrogs, should be injected with ca. 0.5 cc of the solution. Frogs of larger or smaller size should be injected with amounts scaled up or down relative to the amount used for adult Gray Treefrogs. Once injected, adult frogs should be placed into a container with a moist paper towel at 30°C for 10–12 h (Bogart 1967).

Once the specimens (either tadpole or adult frog) have been subjected to the colchicine solution for the correct time, they should be sacrificed by the application of Orajel® to the top of the head (Altig 1980). Once sacrificed, the specimens can be dissected and tissue samples may be taken from various locations on the specimen. Leg buds, gills, and intestinal tissue samples were the most successful from tadpoles and intestinal tissue worked best for adult frogs. The tissue sample should be no longer than 0.5 cm in length and should be placed in a small vial containing about 10 times their volume of 0.4% KCl hypotonic solution and should be allowed to sit for 20–30 min (Kligerman and Bloom 1977). Transfer the tissue into 2–3 changes of fixative (3:1 ethanol:acetic acid solution) for ca. 30 min each time (Kligerman and Bloom 1977).

Mount chromosomes on slides using heat fixation. This can be accomplished by heating blank slides 46–48°C. The tissue sample should then be placed into a separate vial containing 100 µl 50% acetic acid (Kligerman and Bloom 1977). Tap the vial for 60–90 sec to break apart the tissue and form a cell suspension. Using a pipetman, draw the cell suspension into the tip and expel it onto the slide. Quickly withdraw the suspension back into the pipet tip, leaving as little liquid on the slide as possible.

Stain chromosomes with 4% Geimsa made up in 0.01 M phosphate buffer at pH 7 for 10 min. Air-dry the slides and place in xylene for 10 min to remove excess water. Once dried, the slides can be completed by using Permount and a cover slip over the fixed sample.

Acknowledgments.—We thank P. Villani for assisting with digital images of the chromosome spreads. This study was supported by two grants from the Augustana Research Foundation, Augustana College: Bernsten Award to LG, and Faculty Research Grant to SBH.

Passive integrated transponders are small microprocessors encased in glass that transmit a unique identification number to an electronic reader when the tag is activated by the reader with a low frequency radio signal at close range (Balazs 1999). PIT tags were originally developed to census fish populations (Boarman et al. 1998) and to track fish migration (Prentice et al. 1987). However, their use has become widespread in the identification and monitoring of individuals of other vertebrate groups. PIT tags have been successfully used in studies of mammals, such as otters, rats, bats, mice, ferrets (Elbin and Burger 1994), and voles (Harper and Batzli 1996). PIT tagging has been used on a variety of amphibians and reptiles, including lizards, alligators, frogs, and toads (Elbin and Burger 1994), neonatal snakes (Keck 1994), caiman hatchlings (Dixon and Yanosky 1993), and rattlesnakes (MacGregor and Reinert 2001). In freshwater turtles (Elbin and Burger 1994; Buhlmann and Tuberville 1998), and sea turtles (Balazs 1999; McDonald and Dutton 1996), PIT tags have also been proven successful. In a study of PIT tag utility, Camper and Dixon (1988) tagged 24 individuals of eight different species of freshwater turtles, including eight *Trachemys scripta elegans*.

PIT tag effectiveness has been discussed in a number of different studies, including one on the Pine Snake (Elbin and Burger 1994), and another on a large group of Desert Tortoises (Boarman et al. 1998). Both of these studies came to the conclusion that PIT tags were an efficient and reliable method of marking and tracking their respective subjects. There have been relatively few reports on tag retention in freshwater turtles, Buhlmann and Tuberville (1998) being the only one with large sample sizes known to us. Balazs (1999) discussed some of the advantages and disadvantages of tagging sea turtles with PIT tags. Advantages of the tags include virtually no loss or damage over time from breakage or corrosion, which offers the possibility of long-term reliable retention in sea turtles. Disadvantages include migration within body tissue, inability to detect a tag without a reader, and overall higher cost for the PIT tags (US $6.00 each) and reader (~ US $400) as compared to external tags. PIT tags appear to have no adverse effects upon the freshwater turtles into which they are injected (Buhlmann and Tuberville 1998).

During the course of a study of the impact of the invasive turtle *Trachemys scripta elegans* on native *Pseudemys floridana* and *P. nelsoni* populations in St. Petersburg, Florida, PIT tags were injected into each captured turtle in order to recognize individuals of all three species. Our goal here is to examine tag retention and tag movement in the turtles marked for that study and to report on the utility of a specific injection site between the pelvis and plastron. Furthermore, we assess the impact of PIT tags on reproduction in female turtles.

Since April of 1998, retention and movement of PIT tags from the site of implantation in turtles of three species were studied using x-rays. Throughout the study, x-rays were taken to determine if captured females were carrying eggs (Gibbons and Greene 1979). This also allowed the presence and movement of PIT tags to be observed. Most of our data are from adult female *T. scripta elegans*; however, small samples of female *Pseudemys floridana* and *P. nelsoni* were also tagged, recaptured, and x-rayed, as were small samples of males of all three species. Females were kept overnight to be x-rayed at a veterinarian's office. Three males, two *P. floridana* and one *T. s. elegans*, were x-rayed to confirm the location of the PIT tag after a number of years. Turtles were released into the ponds from which they were captured.

Turtles were captured using hoop traps (Nylon Net Co.) in six ponds on the Eckerd College campus, St. Petersburg, Florida (Emer 2004; Hutchinson 1992). Upon first capture, each turtle was given a unique three-letter code that was drilled into their marginal scutes (Gibbons and Greene 1979), which was used to identify turtles in case of PIT tag loss. Beginning in April 1998, PIT tags were used along with scute drilling. Prior to injection, the turtle was placed on its carapace. The tag was injected with a 13-gauge needle into muscles and connective tissue between the pelvis and plastron just lateral to the midline. This location was chosen because it is between two plates of bone that move little relative to one another, subjecting the tag to the least disturbance possible. The needle was inserted just through the skin into the tissue dorsal to the xiphiplastron and ventral to the ischium, lateral to the cloaca. The tag was delivered into connective tissue and muscle by a plunger built into the syringe. Care was taken to avoid any inadvertent lateral tail movement during insertion of the needle. When turtles were recaptured, PIT tags were read using an AVID, Inc. scanner by placing the scanner along the interanal seam of the plastron.

The locations of the PIT tags were followed using x-rays in a total of eleven female *T. s. elegans*. In these turtles, the PIT tags stayed in essentially the same location into which they were injected. These eleven females had been PIT tagged over a period of five months (April–June 1998). They were found to have retained the tags at subsequent captures, ranging from 30 days to 48 months later. In two females, the PIT tags moved from one side of the midline to the other over a period of 16 days to 16 months, respectively. Another female died during the course of the study of causes not related to the tag implant; this female had lost a PIT tag and had a second one injected. It is believed that this turtle lost the first tag because it was placed too far posterior of the ideal injection site and was lost through the injection site. The second tag was placed in the proper position and was retained for 45 months until her death. At least two females developed, carried, and laid clutches of eggs without affecting the position of the PIT tag, nor did the tag appear to interfere with the normal reproductive process. One male *T.s. elegans* was x-rayed 50 months after implantation of the PIT, and the tag was found to be in the same location into which it was injected originally. Seventeen other males were tagged, and retained their PIT tags without loss between captures spanning from 73 days to 35 months. All tags were readable at each recapture.

PIT tags in a total of eight *Pseudemys floridana* and three *P. nelsoni* were also monitored. Two female and six male *P. floridana* were tagged, but only one female and two males were subsequently x-rayed. Two males were x-rayed at recapture; one had retained the PIT for 36 months, and the other for 14 months between captures (Fig. 1). The female was tagged and x-rayed on first capture, but was not recaptured. In the turtles that were checked with the scanner but not x-rayed, tags could be read at subsequent recaptures, spanning periods of 20–30 months. Only one of three *P. nelsoni* has been tagged and subsequently recaptured. This adult female had retained the PIT tag for 32 months.

FIG. 1. X-ray of male *Pseudemys floridana* showing the location of the PIT tag; located laterally and to the right of the midline.

It appears that PIT tags are reliable if properly injected into the location described above, and the tags do not get lost when placed in connective tissue where very little movement occurs. In this study, the tags did not appear to be more effective than carapacial drilling. However, if tracking of large numbers of turtles were necessary (Boarman et al. 1998), or for tagging of softshell turtles, PIT tags would be more efficient. Another consideration with the use of the PIT tag system is that while electronic readers cost on average US $400, PIT tags remain expensive at US $6 per tag. This may affect the use of PIT tags in a study that monitors large numbers of animals. The tags are an easier and quicker method of marking turtles than scute drilling, and while carapacial scute markings may grow back after one to two years in juvenile *Pseudemys* (Meylan, unpubl.), the PIT tags remain in place and are readable for at least 50 months after implantation. The lifespan

of a PIT tag is theoretically the lifetime of the animal; because a PIT tag is a passive marking system, as long as it remains inside the animal, it should be readable. The first successful PIT tag was made in the early 1990s, and is still working today, so the lifetime is at least 14–15 yrs (AVID, Inc., pers. comm., 16 January 2004). PIT tags are easier to read and provide a means of confirming drilling or notching, thus leading to fewer errors when large numbers of collaborators collect data, or when large numbers of animals are used in a study.

Acknowledgments.—This study has been supported by Eckerd College. Many thanks to Diana Huestis, the Eckerd College Herpetology Club, and Drs. Richard Wilkes and Shawna Greene at Bay Moorings Animal Hospital. Thanks also to Jim Dixon for reviewing and providing valuable commentary.

Despite being such a large, conspicuous snake, the King Cobra (*Ophiophagus hannah*) was not described until 1836 (Cantor 1836). To date, little is known regarding its natural history and reproductive biology. For a summary of field observations of reproductive behavior see Table 1.

Examination of reproductive data reveals some interesting trends. In general, mating occurs in the post-winter warming period, egg development within the female occurs in the tropical summer, nesting and egg laying coincide with pre-monsoon showers, and hatching occurs at the peak of the monsoon. Captive snakes in locales far removed from monsoon seasons remain faithful to this breeding cycle. While the monsoon in Chennai (where no King Cobras occur) is in the winter, reproductive behavior in our captive King Cobras followed the southwest monsoon cycle of southwestern and northeastern India.

In 1996, we established a conservation-oriented captive-breeding program for King Cobras at the Madras Crocodile Bank/Centre for Herpetology (MCB/CFH). The objectives were to (a) develop methods and a protocol for the breeding of King Cobras in India, and (b) to offer captive bred King Cobras to zoos in order to discourage the taking of animals from the wild. Herein, we report husbandry and captive breeding information along with previously published data.

Husbandry.—In 1996, MCB/CFH received seven (three males and four females) adult King Cobras; four of these were on breeding loan from Indian zoos and three had been seized by the Wildlife Department from snake collectors.

A block of eight rooms was constructed of brick and mortar with light roofing. Each room measured 3.5 x 1.5 x 2 m (L x W x H). At the rear of each room (opposite the door) is a 100-mm air duct connected to an air conditioner, which from April to September (1000–1600 h) creates a temperature gradient of about 6°C, increasing to 30°C towards the door. Outside the rooms, the ambient temperature may reach 40°C + during this period. Throughout the rest of the year (cooler months with lows of 18– 20°C), a heating pot containing a 25-watt bulb placed in an upturned mud pot is situated in the rear corner of each room. The surface temperature

TABLE 1. A summary of *Ophiophagus hannah* breeding data. Incubation period is recorded from oviposition to first hatching.

Mating	Nesting/laying	Gestation (days)	Hatching	Incubation (days)	Captive/wild	Source

of the exposed section of the pot averages 31°C. Each room has a large wooden hide box measuring 60 x 60 x 30 cm with a lid and a small sliding entry door (12 x 20 cm).

Reproduction.—After laying eggs on the open pile of leaves, the females gathered more leaves and covered the eggs with a thick layer. They then crawled on top of the nest and burrowed into the leaves. These two cavities (one for the eggs and another for the female) are probably the "two chambers" described by Mustill (1936). In the wild, rain and the weight of the female compacts the nest, and towards the end of incubation the female often lies exposed on top of the nest (as observed by Leakey 1969 and Whitaker 1977). See Table 2 for summary of nest data.

A relationship between female length and clutch size in *Ophiophagus hannah* has been postulated (Leakey 1969). Correlation between both brood size and clutch size in oviparous elapids from Australia is known (Greer 1997). Using linear regression analysis we observed a linear relationship between female total length and clutch size. Localities for specimens examined are northeastern and southwestern India, Thailand, Burma, and Malaysia. From this relationship, we developed equations for predicting female total length from clutch size (formula 1) and clutch size from female size (formula 2, SEE = standard error of the estimate).

(1) Female total length = 126.457 + 5.244 x clutch size (r^2 = 0.79; N = 23; SEE = 21.8);

(2) Clutch size = -13.121 + 0.151 x female total length (r^2 = 0.79; N = 23; SEE = 3.69).

The 23 samples used were derived from a larger population. Hence samples from the same population would yield different SEEs. In order to apply the SEE to the population and derive estimates of total length from clutch size (formula 1), and clutch size from total length (formula 2), a Students t-distribution was used. The 95% confidence limit (t = 2.080; df = 21) would for equation 1 be ± 45.35 cm, while it would be ± 7.68 eggs for equation 2. Hence, using equation 1 and assuming a clutch size of 22 eggs, predicted total length can be calculated as female total length = 126.457 cm + 5.244 cm x 22 = 241.83 cm. Calculating SEE ($t_{.05}$) results in 21.8 cm(2.08) = ± 45.34 cm. Therefore, a clutch size of 22 eggs has a 95 % confidence limit that a female would be 241.83 cm long (± 45.34 cm).

Both equations have management implications. In such cases where females are often not observed at nest locations, one may utilize formula 1. If a mature female is captured, her probable clutch size may be predicted from her

TABLE 2. Nesting data for *Ophiophagus hannah* from the Madras Crocodile Bank (CS = clutch size; and nest temperature in °C).

CS	No. viable (% of CS)	No. hatched (% of viable eggs)	Incubation periods (days)	Oviposition time (h:min)	Nest temperature
18	18 (100)	11 (61.1)	57–61		
37	34 (92.0)	14 (41.1)	58–63	4:35	31.2–32.3
16	12 (75)	5 (41.7)	57–59	3:45	29.8–33.1
18	0 (0)	0 (0)		4:03	29.2–32.8

dimensions by formula 2. The r^2 value (0.79) is high, and this can be interpreted by stating that 79% of variation in clutch size/female total body length was explained by the other factor. Additional factors that might account for the residual 21% are female body condition and environmental effects. Regression equations were significant in both cases (ANOVA; F = 78.92, N = 23 for equation 1, and F = 79.89, N = 23 for equation 2). The relationship between female total body length and clutch size is illustrated in Fig. 1.

TABLE 3. *Ophiophagus hannah* growth rate summary based on snakes hatched at Madras Crocodile Bank. Age in months, followed by number of males, females, and unsexed. TL = mean total length in centimeters.

Age		Male TL (± SD)	Wt (grams)	Females TL (± SD)	Wt (grams)
6	(0.0.30)	~80		~80	
12	(0.0.26)	~150		~150	
55	(4.11.0)	234 (37)	1587 (916)	210 (25.6)	1036 (225)
62	(3.7.0)	239 (47)	1800 (1562)	216 (25.23)	1000 (200)

The eggs were elongate and leathery, 3–5 cm in length, and 2–3 cm in width. As many as 51 eggs have been reported in a clutch (Oliver 1956). Our snakes produced 16–37 eggs. Each egg was set up individually. Eggs were kept on a vermiculite and water mixture, 1:0.8 by weight. Incubation temperatures ranged from 27.5°C to 33.0°C with a humidity of 85–90%. Each jar was opened daily to allow fresh air exchange.

Eggs hatched in 57–63 days, a shorter incubation period than reported for other captive breedings (70–75 days; Burchfield 1977; Dattatri 1987; Oliver 1956). We attribute shorter incubation time to higher incubation temperatures.

Neonate Care.—Upon hatching, animals were housed according to standard setups for most neonate snakes. This included individually housing animals in small plastic boxes with newspaper substrate and cage furniture. The only exception was lack of a water bowl (neonates were soaked separately).

Because many captive King Cobras hatchlings initially refuse to feed (Burchfield 1977; Dattatri 1987; Leakey 1969), we found it necessary to assist-feed our animals with pinkies (*Mus boodaga*) and small skinks (*Riopa punctata*).

Long-term successful maintenance of hatchling King Cobras requires a clean, humid environment with optimal temperature range of ca. 25–33°C. These conditions facilitated rapid growth (Table 3).

As of July 2003, ten of the offspring have been sent to five zoos in India, and a pair to the National Zoological Gardens, Sri Lanka. King Cobras have also been bred at several US zoos (Gladys Porter Zoo, Riverbanks Zoological Park, Toledo Zoo, and Black Hills Reptile Gardens). Apart from data gleaned from captive animals, the reproductive biology and status of this species in the wild remains poorly known

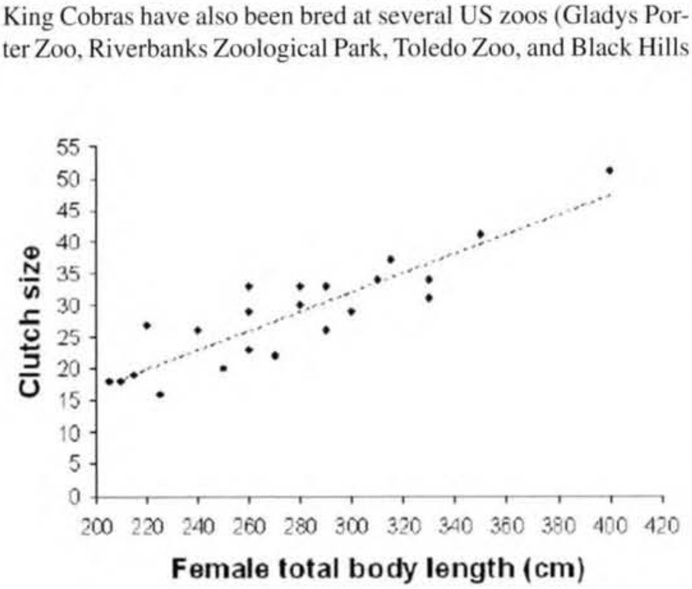

FIG. 1. Relationship between female total body length and clutch size in *Ophiophagus hannah* (N = 23).

Acknowledgments.—We thank the following people and organizations for their contributions, making this work possible. The Central Zoo Authority, Ministry of Environment and Forests (Govt. of India), the Wildlife and Forest Departments of Pondicherry, Tamil Nadu, Kerala, Gujarat and Karnataka provided permits for transferring king cobras to the MCB/CFH. The Ahmedabad Zoo, Sundervan Nature Park, Malampuzha Snake Park, and Mysore Zoo provided snakes for this project. Thanks to Harry V. Andrews, Rupali Ghosh, Gowrishankar, P. O. Naseer, Samir Whitaker, Colette Adams, Scott Pfaff, and National Geographic Television for assisting in a variety of ways. Special thanks to K. Munusamy (Sr.) for the supervision of construction of breeding enclosures, and to snake handlers S. Sampath and V. Mari. Brian Stacy provided valuable medical advice, while Matthew C. John provided veterinary services. We are grateful to the Trustees of the Centre for Herpetology.

NATURAL HISTORY NOTES

The Natural History Notes section is analogous to Geographic Distribution. Preferred notes should 1) focus on observations with little human intrusion; 2) represent more than the isolated documentation of developmental aberrations; and 3) possess a natural history perspective. Individual notes should, with few exceptions, concern only one species, and authors are requested to choose a keyword or short phrase which best describes the nature of their note (e.g., Reproduction, Morphology, Habitat, etc.). Use of figures to illustrate any data is encouraged, but should replace words rather than embellish them. The section's intent is to convey information rather than demonstrate prose. Articles submitted to this section will be reviewed and edited prior to acceptance.

Electronic submission of manuscripts is requested (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Authors without the ability to send manuscripts electronically may supply hard copy instead. Figures can be submitted electronically as JPG files, although higher resolution TIFF or BMP files will be requested for publication. If figures cannot be provided in this format, you may send them to the section editor for scanning. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ssarherps.org/HRinfo.html. Manuscripts should be sent to the appropriate section editor: **Marc P. Hayes** (amphisbaenids, crocodilians, lizards, and *Sphenodon*; mhayesrana@aol.com); **Charles W. Painter** (amphibians; cpainter@state.nm.us); **Andrew T. Holycross** (snakes; holycross@asu.edu); and **James Harding** (turtles; hardingj@pilot.msu.edu).

Standard format for this section is as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother [2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. Herpetol. Circ. 29:1–82; available online at <http://herplit.com/SSAR/circulars/HC29/Crother.html>]; for Mexico as it appears in Liner [1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*, Herpetol. Circ. 23:1–113]), KEYWORD. DATA on the animal. Place of deposition or intended deposition of specimen(s), and catalog number(s). Then skip a line and close with SUBMITTED BY (give name and address in full—spell out state names—no abbreviations). (NCN) should be used for common name where none is recognized. References may be briefly cited in text (refer to this issue for citation format).

Recommended citation for notes appearing in this section is: Lemos-Espinal, J., and R. E. Ballinger. 1994. *Rhyacosiredon leorae*. Size. Herpetol. Rev. 25:22.

CAUDATA

AMBYSTOMA CALIFORNIENSE (California Tiger Salamander). **PREDATION.** Although a variety of predators likely feed on *A. californiense* larvae, few have been reported (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington D.C., 586 pp.; Balfour and Stitt 2003. Herpetol. Rev. 34:1). On 12 April 2002, at 1230 h, we observed a pair of adult American Avocets (*Recurvirostra americana*) land at a shallow (ca. 20 cm), 0.011-ha, seasonal pool situated in non-native annual grassland near Brentwood, Contra Costa County, California, USA (37°55'18.5"N, 121°45'28.7"W). Both birds immediately began feeding by aggressively sweeping their bill side to side in shallow water. Within 2 min, one American Avocet moved quickly out of the pool with an *A. californiense* larva in its bill. To confirm our observation, we immediately flushed the birds and the larva was dropped ca. 30 m away. We recovered the late-stage larva (98 mm TL; 52 mm SVL), took photographs, and returned it to the pool, although a small laceration near the left gill may have been fatal. A digital photograph of the larva was deposited in the Natural History Museum of Los Angeles County (LACM PC 1389).

On 31 March 1998, at 0830 h, we observed a Forster's Tern (*Sterna forsteri*) take a small *A. californiense* larva from a deep (ca 1.7 m), ca. 0.28-ha, seasonal stockpond situated in non-native annual grassland and salt grass (*Distichlis spicata*) near Byron Airport in southeastern Contra Costa County, California, USA (37°49'13"N; 121°37'42"W). The Forster's Tern captured the larva by plunging from a height of ca. 10 m. Ten minutes later, after preening on the ground during a light rain, another *A. californiense* larva was caught in the same way. Binoculars (10 power) were used to identify both larvae, which were briefly held in the bill before being consumed. On 17 March 1998, aquatic sampling of the stockpond with a seine detected only larval *A. californiense* that averaged 18.2 mm SVL (range: 8–30 mm SVL; N = 20).

Submitted by **MARK L. ALLABACK** (e-mail: mawildlife@aol.com), **DAVID M. LAABS**, Biosearch Associates, P.O. Box 1220, Santa Cruz, California 95061, USA; **SARA E. HIGGINS**, 822 Encino Drive, Aptos, California, USA; and **TED P. WINFIELD**, Ted Winfield & Associates, 1455 Wagoner Drive, Livermore, California 94550, USA (e-mail: tpw_jr@pacbell.net).

AMBYSTOMA CALIFORNIENSE (California Tiger Salamander). **FUNGAL INFECTION**. First described as a new species in 1999 (Longcore et al. 1999. Mycologia 91:219–227), *Batrachochytrium dendrobatidis* is a recently emerged chytrid fungus that has been identified as a causative agent in selected amphibian declines around the world (Berger et al. 1998. Proc. Nat. Acad. Sci. USA 95:9031–9036; Daszak et al. 1999. Emerg. Infect. Diseases 5:735–748; Bosch et al. 2001. Biol. Cons. 97:331–337). To date, this pathogen has been reported in the wild from 8 anuran species and the Santa Cruz Long-toed Salamander (*Ambystoma macrodactylum croceum*) in California (Speare and Berger 2000. Global distribution of chytridiomycosis in amphibians [11 November]. (http://www.jcu.edu.au/school/phtm/PHTM/frogs/chyglob.htm); Vredenburg and Summers 2001. Herpetol. Rev. 32:151–152). It has also been reported in Sonoran Tiger Salamanders (*A. tigrinum stebbinsi*) in Arizona (Davidson et al. 2003. Copeia 2003:601–607). Herein, we report the first case of *B. dendrobatidis* in California Tiger Salamanders (CTS; *A. californiense*), a urodele currently federally listed as Endangered in parts of California (Anonymous 2000. CFR 65:7241–57264; Anonymous 2002. CFR. 67:47726–47740).

A total of 11 larval CTS from five different ponds in Joseph D. Grant County Park, Santa Clara County, California, USA (37°20'29"N, 121°42'17"W; elev. 650 m) were collected, preserved in alcohol, and later examined. We removed small pieces of toe skin from each specimen and microscopically examined unstained tissue for *B. dendrobatidis* zoosporangia. Two specimens from two different ponds were positive for the pathogen, as indicated by the presence of non-hyphal spherical zoosporangia with one or more inoperculate discharge papillae (Longcore et al. 1999. Mycologia 91:219–227) (Fig. 1). These data demonstrate that the potentially harmful pathogen is present in wild populations of CTS. Thus, translocating CTS to areas containing amphibian species that are mortally affected by *B. dendrobatidis* could have profound negative effects on our endemic herpetofauna. As translocation is often encouraged by state and federal agencies as part of rescue efforts (Dodd and Seigel 1991. Herpetologica 47:336–350), testing for this pathogen should be a routine part of the protocol prior to any CTS relocation attempts.

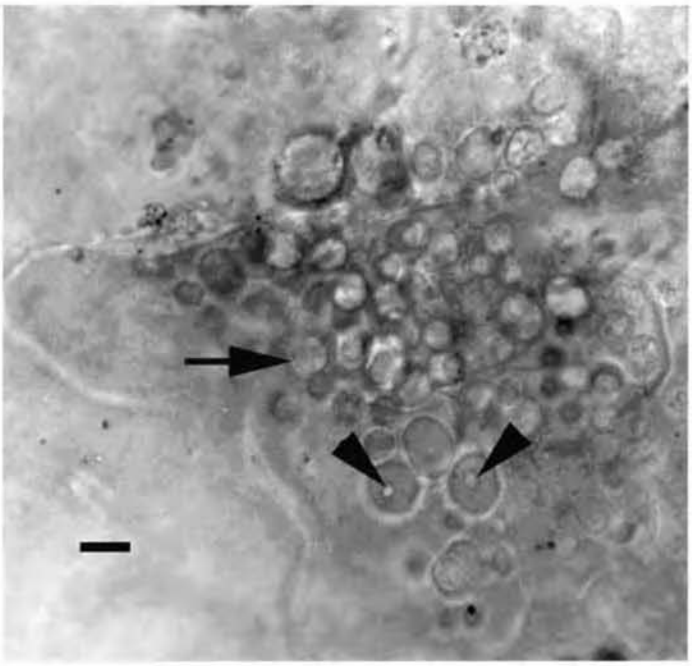

FIG. 1. Unstained toe skin from *Ambystoma californiense*; arrow indicates thin wall within thallus of *Batrachochytrium dendrobatidis*; arrowheads indicate open discharge papillae (*fide* Longcore, *op. cit.*). Size bar = 10 µm.

Permission to collect CTS specimens was authorized by permits issued by the California Department of Fish and Game (801160-02) and the County of Santa Clara Parks and Recreation Department to Gretchen E. Padgett-Flohr. Specimens (CAS GEF101-GEF112) are deposited at California Academy of Sciences, San Francisco, California. We thank Daniel Clark, Karen Coffer, Molly Goble, Mark Jennings, Maya Khosla, Don Rocha, and Jeffrey Wilcox for assistance in the field, and Mark Jennings for suggestions on the manuscript.

DESMOGNATHUS AENEUS (Seepage Salamander). **MAXIMUM SIZE**. *Desmognathus aeneus* is one of the smallest salamanders native to North America, reaching a previously documented maximum SVL (measured to anterior end of vent) of 29 mm (Harrison. 1967. Amer. Midl. Nat. 77:356–370).

On 28 October 2003, we collected an adult male *D. aeneus* (deposited at the Georgia Museum on Natural History, GMNH 49482) near Stanley Creek at Rock Creek Road, Gilmer County, Georgia (within the Rich Mountain Wilderness Area) that surpassed the previous record length. Following preservation, this specimen measured 31.20 mm SVL (measured to anterior vent; 33.48 mm to posterior vent) and 64.50 mm TL; however discoloration of the posterior end of the tail revealed regeneration. Additionally, the specimen has three testicular lobes on each side, which is indicative of a very old individual (Harrison, *op. cit.*).

We thank Thomas Floyd and Elizabeth McGhee for verifying measurements.

JENSEN**, Georgia Department of Natural Resources, Nongame-Endangered Wildlife Program, 116 Rum Creek Drive, Forsyth, Georgia 31029, USA (e-mail: john_jensen@dnr.state.ga.us), and **CARLOS D. CAMP**, Department of Biology, Piedmont College, 165 Central Avenue, Demorest, Georgia 30535, USA.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander). **NESTS.** *Hemidactylium scutatum* is a small secretive salamander associated with bogs and mossy forests. Communal nesting has been reported in that species, in which nests are highly associated with Sphagnum moss. Nevertheless, despite the numerous notes about new localities for that species in Québec, Canada, at its northeastern range limit, no data about the ecology of this salamander are available. Here we report the nests of the species at four different localities in Québec, with inferences about the occurrence of communal nesting, based on the number of females and eggs at nest, and the characteristics of the nests (height, water depth, and substrate).

The sites were located on the Canadian Shield, north of St. Lawrence River (45°39'N, 75°03'W; 46°36'N, 72°36'W; 46°33'N, 72°24'W; 46°45'N, 71°19'W; NAD83 map datum). They were visited in May 2002 and 2003. Nests were sought by turning over mats of mosses, Sphagnum, and grass adjacent to stagnant water, in habitats where we previously found *Hemidactylium*. Every time a nest was found, the eggs were counted, if possible without touching the females, though most females were put in a small plastic bag with Sphagnum during the count of eggs. This did not seem to disturb females, and only one lost its tail during the procedure. The height of the nests above water and the water depth were measured using a metric plastic rule.

A total of 107 nests of *H. scutatum* were found during May in small pools where Sphagnum occurs, bordered by mixed woods. The average number of eggs in a nest was 28.1 (range 4–114) and in only 4.7% of nests did we observe two females. Considering an average clutch of 40 eggs per female (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington and London, p. 293), only 12.2% of the nests were communal. Nevertheless, if we consider the maximal possible known number of 80 eggs/female (Wood 1953. Amer. Nat. 87:77–86) only 2.8% of all nests are certainly not from a single female. Sphagnum is the most often used substrate for deposition of eggs, occurring in 95.3% of all nests and the only substrate in 88.8% of cases. Only five nests were found without any Sphagnum—four in mosses and one in grass. The height of nests from water varied from 4.5 to 18 cm (average 11.2 cm) and the depth of water under nests varied from 2.3 to 19 cm (average 9.1 cm).

These data help in understanding the ecology of *H. scutatum* at its northeastern range limit. Although commonly described as a communally nesting species, this seems not to be the standard rule in Québec. Maybe this is a consequence of smaller populations, near their range limit, allowing many potential nesting sites for each female.

We thank F. W. Schueler for useful comments on the first draft of this note.

PSEUDOTRITON RUBER RUBER (Northern Red Salamander). **TREE CLIMBING.** On 10 June 2003 at 1830 h in a second growth forested stream/seep area 1.5 km WSW of Ward Chapel, Tennessee (Coffee Co., 35°28'07"N, 86°11'32"W), a recently metamorphosed *Pseudotriton ruber ruber* (42 mm SVL, 68 mm TL) was observed 90 cm above ground on a 20 cm diameter *Carya* sp. (hickory). The salamander was oriented perpendicular to the vertical axis of the tree and remained motionless for 10 min after which time measurements were taken. The forest floor and tree were wet following the passage of a thunderstorm that moved through the area 30 minutes before the observation producing rainfall in excess of 1 in (2.54 cm). Air temperature was 23°C and a light rainfall was detected at the time of observation.

A few ground-dwelling plethodontids are known to be effective foragers utilizing vegetation. Jaeger (Copeia 1978:686–691) reported *Plethodon cinereus* climbing plant stems to forage but only during periods of high humidity on rainy nights due to risk of desiccation. Recently, *Plethodon glutinosus* was reported climbing a pine tree during a rainy night from Coffee Co., Tennessee by Regester and Samoray (2002. Herpetol. Rev. 33:45). This observation is believed to be the first report of tree climbing by *P. ruber ruber*.

ANURA

BUFO BOREAS (Western Toad). **SEED DISPERSAL.** On 22 Aug 2003, during surveys as part of an amphibian monitoring program in Elk Island National Park, Alberta, Canada (53°36'N, 112°53'W) we captured two young-of-the-year *Bufo boreas* with seeds attached to their heads. Both individuals had a single achene of the nodding beggartick (*Bidens cernua*; Asteraceae) embedded in the sphenethmoid and frontoparietal regions of the head between the eyes. The beggartick is a native annual common on muddy shores of lakes and ponds in Elk Island (Griffiths and Cotterill 2002. Vascular Plant Species List: Elk Island National Park. Unpubl. report). Its seeds are 5–7 mm long and bear 2–4 barbed awns used in a "stick-tight" dispersal strategy in late summer (Johnson et al. 1995. Plants of the Western Boreal Forest and Aspen Parkland. Edmonton). Initially we did not recognize the seed and pulled the achene from the head of one of the toads, which was then released at the capture site. The spines at the base of the achene were bloody after removal. We were unable to remove the achene from the second animal (Fig. 1), and retained this individual in captivity for observation. It died on 7 Sept 2003. The mean length of 30 individuals measured at the same site was 18.7 mm (range: 15.5–21 mm); the individual with the seed in its head measured 13.0 mm in length (measured after preservation in 70% ethanol). The animal did not appear emaciated or stressed when it was captured, and was observed attempting to eat small crickets we provided in captivity. The toad did not exhibit any obvious signs of distress, and was never observed trying to remove the seed.

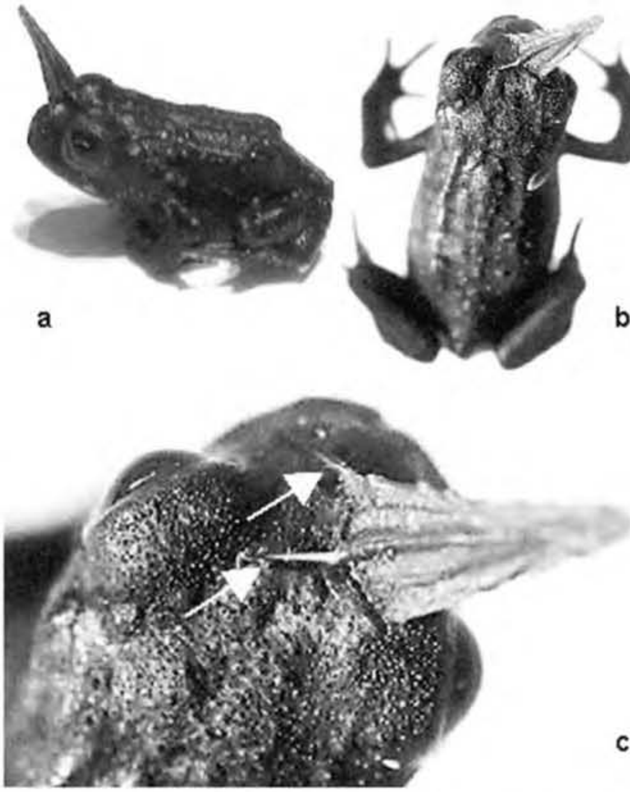

FIG. 1. Living young-of-the-year *Bufo boreas* with achene of nodding beggartick attached to head. (a) Lateral view; (b) dorsal view; (c) close-up of seed insertion point on head, with two of the barbed awns of the seed visible (arrows). The animal was captured 3 days prior to the photographic session.

We examined a total of 293 Western Toads, 755 Wood Frogs (*Rana sylvatica*), and 408 Boreal Chorus Frogs (*Pseudacris triseriata*) during the summer of 2003 in and around Elk Island National Park; 87 of these were YOY Western Toads from the same pond as the seed-bearing individuals. None of the other anurans examined bore seeds. Although seed dispersal by vertebrates is a well-known and important process in many ecosystems, seed dispersal by amphibians seems rare. This is the first report of an anuran passively transporting plant seeds. Presumably the toads pick up the adhesive achenes as they move through plants growing on the shores of ponds and lakes.

Thanks to R. Mandryk for photographing the specimen. Parks Canada allowed access to the study site. Ducks Unlimited Canada, Friends of Elk Island, and the Parks Canada Species at Risk Recovery Action and Education Fund provided support for amphibian sampling at Elk Island.

BUFO BOREAS HALOPHILUS (California Toad) and ***RANA CATESBEIANA*** (American Bullfrog). **AMPLEXUS.** Attempted mating between native and introduced anurans has been documented for a number of species. For example, North American anurans such as *Rana aurora* have been observed in amplexus with introduced *R. catesbeiana* (Storm 1952. Herpetologica 8:108). We here provide the first documentation of *Bufo boreas halophilus* in amplexus with *R. catesbeiana*.

On 21 June 1997 while conducting a herpetological survey of Cache Creek in the vicinity of Rumsey, Yolo County, California (USA), we observed three instances of male *B. b. boreas* attempting to mate with juvenile *R. catesbeiana*. Male *Bufo* were calling in a number of ponds and oxbows along Cache Creek in the evening after 0015 h. *Rana catesbeiana*, which are introduced to California, are common in this part of the creek. Upon careful examination of several clumps of salt-cedar (*Tamarix* sp.) along the stream, we observed three separate instances of adult male *B. b. halophilus* in amplexus with *R. catesbeiana*. Two of these amplexing pairs were captured intact (pair #1: *Bufo* 91.0 mm SUL, 59.0 g/*Rana* 88.0 mm SUL, 54.6 g; pair #2: *Bufo* 98 mm SUL, 86.8 g/*Rana* 84 mm SUL, 51.2 g), while the third pair separated and escaped. These four specimens (CAS 203248–9, 203160–1) were all healthy individuals, although the male *Bufo* had rubbed the undersides of the *Rana* raw where they had amplexed with their thumbs and forelimbs. The repeated observations of *B. b. halophilus* in amplexus with *R. catesbeiana* indicate that this is not an isolated incident during the breeding season and further show that *R. catesbeiana* can have a negative effect on native anurans by interfering with reproduction. This is significant as most detrimental effects of introduced bullfrog populations center on their voracious predatory habits (Cook and Jennings 2001. Herpetol. Rev. 32:182–183), their ability to displace other anurans from suitable aquatic habitats (Kiesecker and Blaustein 1997. Ecology 78:1752–1760), and their effects on native gartersnakes (*Thamnophis* spp.) as potential food items (Kupferberg 1994. Herpetol. Rev. 25:95–97).

ELEUTHERODACTYLUS RANOIDES (NCN). **DRY FOREST POPULATION, REFUGE FROM DECLINE?** Amphibian declines in pristine and apparently undisturbed habitats have occurred in many highland areas in tropical Latin America (Young et al. 2001. Cons. Biol. 15:1213–1223). One member of the *Eleutherodactylus* "*rugulosus* group" is *E. ranoides*. Known from lowlands and premontane slopes from eastern Nicaragua to extreme western Panama, it was previously common in the Área de Conservación Guanacaste in northwestern Costa Rica. In at least two herpetological surveys of the same area in 2001 and 2003 no *E. ranoides* were found, even though suitable habitat was explicitly examined in several occasions (D. Laurencio, pers. comm; RP, pers. obs.). Because it had not been recorded since 1987, this species has been listed by the IUCN as Endangered (InfoNatura: Birds, mammals, and amphibians of Latin America [web application]. 2004. V. 3.1. Arlington, Virginia: NatureServe. Available: http://www.natureserve.org/infonatura. Accessed: 23 April 2004). However, Sasa and Solórzano (1995. Herpetol. Nat. Hist. 3:113–126) and Sasa (pers. comm.) reported finding *E. "rugulosus"* in 1994 and 1995 at the lowland (5–20 m elev.) Río Murciélago site in the ACG in Sector Murciélago at the northern base of the Península Santa Elena in the Dry Tropical Forest life zone of Holdrige (Tosi, 1969), though no voucher specimens were collected.

We returned to the Río Murciélago site in May 2003 to confirm these earlier observations. On 24 May 2003 we surveyed ca. 2 km of the banks of the Río Murciélago. This was the end of the dry season, and the habitat was extremely dry but the river was flowing from springs. The temperature of the water in the stream was 28°C. No frogs were found between 1700 and 1800 h, however on our return soon after dusk, we collected eight specimens of *E. ranoides* on rocks and under boulders in the stream in ca. 1 h of search. Specimens were deposited at the Museum of Zoology, University of Costa Rica.

Our findings confirm the observations of Sasa and Solórzano (*op. cit.*) and demonstrate the continued survival of at least one of the five *rugulosus* group species in Costa Rica. We emphasize that the lowland Río Murciélago site is 24 km due W of Volcán Cacao and central to the 80,000 ha of coastal lowland regenerating dry forest that separates the Cordillera Guanacaste from the Pacific Ocean. However, this portion of the Río Murciélago is exceptional for dry forest in having year-round flowing water in a least some portions, though the water temperature in the Río Murciélago is quite high. Historical collections of *E. ranoides* at Volcán Cacao are from sites of much lower water temperatures and much wetter. We hypothesize that the high temperature and six-month dry season at the Río Murciélago site protect the frogs from whatever made their populations decline at Volcán Cacao.

We thank Daniel Janzen, William Eberhard, Alan Pounds, Jonathan A. Campbell, and Bruce Young for comments on the manuscript.

HYLA CHRYSOSCELIS (Cope's Gray Treefrog). **TADPOLE OVER-WINTERING.** Relatively little is known about larval ecology of anurans from northwestern Louisiana. On 10 Nov 2003 we observed 10–12 *Hyla chrysoscelis* tadpoles living in a 30 cm deep, 3-m diam unheated pond with a running fountain and concrete basin located on the grounds of Holy Angel's Residential Facility, about 15 km S. of Hwy 3132 on Ellerbe Rd. in Shreveport, Louisiana (Caddo Parish). Unidentified odonates and bellostomatids were present in the pond. Vegetation included emergent *Equisetum* sp., *Typha* sp., and *Nymphaea* sp. Fallen oak (*Quercus* sp.) leaves and pine (*Pinus* sp.) needles covered the pond's substrate. Two of the tadpoles had fully emerged rear legs. Upon returning to the site 1 Jan 2004, two *H. chrysoscelis* tadpoles with early developing hind limbs were observed actively foraging on the substrate. A third tadpole was observed secluded among pine needles and was lethargic. The calling season for this species continues into late summer and early fall (Dundee and Rossman 1996. The Amphibians and Reptiles of Louisiana, Louisiana State University Press, Baton Rouge, Louisiana). Our observations provide some evidence that this species can facultatively overwinter as a tadpole if needed. This anecdote also represents the first known observation of overwintering in this species. All larvae were returned to the pond after observations. We thank Holy Angel's Residential Facility for access to the pond.

PHYLLOMEDUSA ROHDEI (Leaf-tree Frog). **FIGHT INJURIES?** A population of *P. rohdei* was observed for 84 nights (411 h), during July 1999–July 2000, in a temporary pond ca. 170 m², located in the edge of a forest at Palmital (22°50'S; 42°27'W), Municipality of Saquarema, State of Rio de Janeiro, southeastern Brazil. During breeding activities, agonistic interactions, including escalated aggressive behavior from non-physical to physical encounters (Wogel et al. 2004. Herpetol. Rev. 35:239–243), were common between males in courtship sites. Although males of *P. rohdei* do not have any anatomical weapons that could cause injuries in a fight, several males' backs were covered with scratches. Less severe scratches were observed in only three females (ca. 4%). Similar scratches also were observed in males of *Phyllomedusa burmeisteri* (Abrunhosa and Wogel, *in press*. Amphibia-Reptilia) that engaged in physical combats. At least two hypotheses might explain these observations: 1) the injuries were caused directly by males using their nuptial excrescences during fights, or 2) the injuries were caused indirectly by the surrounding vegetation at the combat site or when males fell down, a common observation when males were fighting.

We thank Flávio N. Ramos for field assistance. This research was supported by CAPES and CNPq.

Submitted by **HENRIQUE WOGEL** (e-mail: hwogel@acd.ufrj.br), and **PATRÍCIA A. ABRUNHOSA**, Museu Nacional / UFRJ, Departamento de Vertebrados, Setor de Herpetologia, Quinta da Boa Vista, São Cristóvão, 20940-040 Rio de Janeiro, RJ, Brazil.

PHYSALAEMUS SIGNIFER (Girard's Dwarf Frog). **COMMUNAL OVIPOSITION.** Communal oviposition is known in several explosive-breeding anurans (Wells 1977. Anim. Behav. 25:666–693). Here, we describe communal egg laying in *Physalaemus signifer* from Reserva Biológica União, Municipality of Rio das Ostras, State of Rio de Janeiro, southeastern Brazil.

A temporary pond ca. 800 m², located in an open area at the edge of the forest (22°25'03"S, 42°02'10"W), was filled with water from November 2002 to the beginning of March 2003 during one year of study (Sept 2002–Aug 2003). After a dry month at the end of the summer 2003, the rain regressed on 17 March, and the pond became a muddy area. On the following night, 10 *P. signifer* formed a chorus at the pond with activity, beginning at 1800 h and lasting until 200 h. Flooded footprints along the edge of the pond had become suitable oviposition sites, and several amplectant pairs were observed using the footprints to spawn. At about 2145 h we observed communal oviposition in *P. signifer*, consisting of five amplectant pairs (mean SVL and mass as follows: males 27.7 ± 1.2 mm SVL, 1.6 ± 0.2 g mass, N = 5; females: 31.0 ± 1.0 mm SVL, 2.2 ± 0.2 g mass, N = 5) spawning inside a footprint 29 x 12 cm, 15 cm depth, and 5 cm of water retention. Wogel et al. (2001. Iheringia 92:57–70) and Weber and Carvalho e Silva (2001. Bol. Mus. Nac. 462:1–6) reported the preference of *P. signifier* for calling and spawning in shallow areas, such as along the margins of a pond. As suggested for *P. ephippifer* (Hödl 1990. Copeia 1990:547–554), the observed communal oviposition in *P. signifer* could result from a shortage of suitable sites for nests.

We thank Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) for fellowships, Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) for financial support, and Reserva Biológica União for logistic support and research permission.

Submitted by **PATRÍCIA A. ABRUNHOSA** and **HENRIQUE WOGEL**, Departamento de Vertebrados, Museu Nacional / UFRJ, 20940-040 Rio de Janeiro, RJ, Brazil; e-mail (PAA): abrunhos@acd.ufrj.br.

PSEUDACRIS CRUCIFER CRUCIFER (Northern Spring Peeper). **AGGRESSIVE BEHAVIOR.** In natural populations males may compete for a limited resource and in pond-breeding anurans, this resource is usually receptive females. Because of direct competition, aggressive bouts between males occur (Duellman 1966. Herpetologica 22:217–221). There have been several reports of aggressive behavior in *Pseudacris crucifer* ranging from territoriality calling (Rosen and Lemon 1974. Copeia 1974:940–950) to grappling events. However, previous reports have documented grappling events and aggressive encounters lasting only a few seconds.

On 8 March 2002, at one of our (JMM) research ponds in Kickapoo State Park, Vermilion County, Illinois (USA), we heard a large intermittently calling chorus of *P. c. crucifer*. Males were calling from perches of emergent vegetation or from low in the water. In some areas where the vegetation was more abundant, males were clustered close together (< 2 m). At ca. 2200 h, we

heard quick trills indicative of *P. crucifer* territoriality calls. After ca. 5 min of searching, we located two males in close proximity (< 0.2 m). They began exchanging territoriality calls in rapid succession. When male one approached male two, the intensity of calling from both males increased. The males oriented toward each other and continued to rapidly call. Male two approached male one and the frogs locked their forearms. At this time, the calling had nearly ceased. Both frogs began pushing each other and in some instances rose slightly up on their hind legs. Wrestling continued for a minute, then male one broke free and turned away. Male two hopped onto his back and they began to jostle for the top position. The jostling continued for ca. 2 min until male one retreated ca. 0.5 m away and held a low posture in the water. Male two returned to the original perch and commenced advertisement calling. After another two to three minutes, male one moved within ca. 0.2 m of male two but remained postured low in the water. Male one remained in this position for about three minutes then swam away.

PSEUDACRIS TRISERIATA (Western Chorus Frog). **REPRODUCTION**. *Pseudacris triseriata* is widespread throughout the upper Yampa River Valley (ca. 2100 m) in northwestern Colorado (Hammerson 1999. Amphibians and Reptiles in Colorado. 2nd Edition. Univ. Press of Colorado and Colorado Division of Wildlife. 484 pp.). After most natural temporary breeding habitats (snowmelt ponds and wet meadows) dry, *P. triseriata* often reproduces in available irrigated meadows. Irrigated meadows have variable and unpredictable hydroperiods, so they may represent risky reproductive sites. Although *P. triseriata* can lay eggs in areas that dry before metamorphosis (Hammerson, *op. cit.*), their success in irrigated meadows is undocumented. Here, I provide preliminary data on *P. triseriata* survivorship in irrigated meadows.

In mid-June 1999, I located nine irrigated meadows that *P. triseriata* were using by following their breeding calls. I monitored sites only if they were currently irrigated or had been within the past week, determined by asking local ranchers. Meadows irrigated by the same ditch were considered independent only if a barrier, such as a flowing irrigation ditch separated them. I searched each site until 2–5 *P. triseriata* egg clusters were found. I flagged each cluster to enable relocation and measured water depth and water temperature at subsequent visits. Sites were visited during early morning, mid-afternoon, or early evening to encompass daytime temperature variation. Dating the initiation of hatching in each egg cluster allowed me to estimate the minimum period from oviposition by counting back 2 days (i.e., the minimum period from oviposition to hatching [Pettus and Angleton 1967. Evolution 21:500–507]). I revisited the meadows every 3–5 days until they dried.

In five (56%) meadows, the water level dropped steadily over the monitoring period and the pools within dried completely. In the remaining four meadows, water depth fluctuated as irrigation water was increased or cut off. Maximum pool temperature ranged from 24–35°C; less than the critical thermal maxima for both piedmont and montane *P. triseriata* tadpoles (Hoppe 1978. Herpetologica 34: 318–321). Although all monitored egg clusters hatched tadpoles, the longest hydroperiod for any of the meadows was 51 days.

As a minimum hydroperiod of ca. 65 days is required from oviposition to metamorphosis (Smith 1983. Ecology 64:501–510), 100% mortality is implied. Because *P. triseriata* began calling at least 30 days prior to initiation of my study (Anne Davis, pers. comm.), substantial breeding had likely already taken place. Therefore, irrigated meadows may have acted as mortality sinks only to late-season breeders. Because *P. triseriata* may lay two clutches per season (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque. 431 pp.), it is possible that the unsuccessful eggs could have been second attempts or that many of the clusters within individual pools were from a single female. These alternatives notwithstanding, these data imply that further investigation of irrigated pastures as mortality sinks is warranted.

RANA PALUSTRIS (Pickerel Frog) and ***AMBYSTOMA MACULATUM*** (Spotted Salamander). **REPRODUCTIVE BEHAVIOR.** Pickerel Frogs and Spotted Salamanders are early spring breeders (Johnson 1997. The Amphibians and Reptiles of Missouri. Missouri Department of Conservation). Although both species may breed in the same pond, the potential for interspecific interference seems small, as both species have widely different reproductive behavior. The salamander mating system is based on olfactory communication, whereas the frog attracts mates via acoustic/vibrational communication. Nevertheless, here I report several instances of inter-species amplexus.

On the night of 7 March 2004, I visited a pond at Three Creeks CA (Boone Co., Missouri, USA). While there were many salamanders in the pond, I found very few *Rana palustris* and did not observe any signs of reproduction (e.g., calling activity or pairs). However, I encountered two different cases in which a male *R.*

FIG. 1. A male *Rana palustris* in amplexus with an *Ambystoma maculatum* of unknown sex, found in central Missouri on 7 March 2004.

palustris had amplexed an *Ambystoma maculatum*. Both pairs were found on the bottom of the pond, in 0.3–0.6 m of water. Although I caught the pairs to examine them and take photographs, the frog maintained the amplexus. Between-species amplexus may incur several costs for both participants. Besides lost feeding opportunity and increased risk for predation there is also the cost of lost mating opportunity.

Two weeks later I visited the site again. This time I found several dozen *R. palustris*, heard males call, and found many egg clutches. I also observed another between-species interaction: as a salamander swam by a male *R. palustris*, the frog turned and amplexed the salamander. The frog quickly released the salamander, however. Further observations are needed to verify whether males are less prone to mating mistakes when conspecific mating opportunities are available.

RANA RUGOSA (Wrinkled Frog). **ENDOPARASITES.** *Rana rugosa* is endemic to Japan, Korea, and northeastern China (Frost [ed.]. 1985. Amphibian Species of the World: A Taxonomic and Geographical Reference. Allen Press, Inc. and The Association of Systematics Collections, Lawrence, Kansas. 732 pp.). It was introduced to Hawaii from Japan in 1895 or 1896 (Bryan 1931. Mid-Pacific Magazine 43:61–64; Oliver and Shaw 1953. Zoologica 38:65–95). The purpose of this note is to report the acanthocephalan *Acanthocephalus bufonis* in *R. rugosa* from Oahu, Hawaii.

One *R. rugosa* (52 mm SVL) was collected 2 May 2000 at Honolulu, Hawaii. It was deposited in the herpetology collection of the University of Michigan, Ann Arbor, Michigan as UMMZ 227582. The esophagus, stomach, small intestine, large intestine, lungs, and urinary bladder were opened and examined separately for helminths under a dissecting microscope. The body cavity was also searched. Two adult acanthocephalans were found in the small intestines. They were each cleared in a drop of concentrated glycerol, identified as *Acanthocephalus bufonis* and subsequently deposited in the United States Parasite Collection, USNPC, Beltsville, Maryland as USNPC 94316.

Acanthocephalus bufonis has an oriental distribution (Kennedy 1982. Can. J. Zool. 60:356–360). It has been reported in *Bufo marinus* from Honolulu, Hawaii by Barton and Pichelin (1999. Parasite 6:269–272). Whether *A. bufonis* reached Hawaii in *B. marinus*, *R. rugosa* or in an intermediate host is not known. *Acanthocephalus bufonis* in *R. rugosa* is a new host record.

TESTUDINES

ACTINEMYS MARMORATA (Pacific Pond Turtle). **DIET.** The diet of *Actinemys marmorata* is known to include a wide variety of items from benthic invertebrates, to plant materials, to carrion (Bury 1986. J. Herpetol. 20:515–521). An opportunistic forager, they often eat the most abundant food resource available (Holland 1985. Herpetol. Rev. 16:112–113). In this note, we provide the first observation of a Pacific Pond Turtle consuming fish eggs.

On 14 May 1997 while conducting a herpetological survey of the Cache Creek drainage in Wolf Creek at the mouth of Quartz Canyon in Lake County, California (USA), one of us (MRJ) observed a spawning aggregation of ca. 100 California Roach (*Lavinia symmetricus*). The fish had schooled into a tight ball ca. 40 cm diam and were spawning over a cobble substrate in 50 cm of water. Closer examination revealed the presence of a Pacific Pond Turtle under this spawning aggregation. The turtle was resting on the cobble substrate and remained motionless except for occasionally retracting its head to avoid being hit by swimming and darting fish. I carefully watched the turtle between 1550–1615 h and soon observed that it was foraging for fish eggs being deposited in the cracks of the substrate. There was no attempt to catch swimming fish as they moved by the turtle's head or bounced off the turtle's head, neck, and front legs. After my observations were completed, I removed the turtle from the spawning aggregation and found that it was an adult female, 145 mm straight-line carapace length.

This record provides another observation of an opportunistic feeding event by a Pacific Pond Turtle; the consumption of fish eggs may also benefit female turtle fitness by providing a rich source of nutrients for their own egg development.

CHELONIIDAE (Marine Turtle). **NEST PREDATION BY BOBCATS**. A variety of mammal species are known as primary predators (initial excavators) of marine turtle nests in Florida (e.g., Stancyk 1982, *In* Bjorndal (ed), Biology and Conservation of Sea Turtles, pp. 139–152. Smithsonian Institution Press, Washington, D.C.). Raccoons (*Procyon lotor*) are probably the most widespread and destructive nest predator (Stancyk, *op. cit.*), depredating up to 95% of nests in some areas, unless control measures are implemented (Bain et al. 1997. Sea turtle nesting and reproductive success at the Hobe Sound National Wildlife Refuge (Florida), 1972-1995. Report to U.S. Fish and Wildlife Service, ARM Loxahatchee NWR). Spotted Skunks (*Spilogale putorius*), Gray Foxes (*Urocyon cinereoargenteus*), Opossums (*Didelphis virginiana*), and Red Wolves (*Canis rufus*) are other native species that depredate nests, while Nine-banded Armadillos (*Dasypus novemcinctus*), Coyotes (*Canis latrans*), feral swine (*Sus scrofa*), and Red Foxes (*Vulpes vulpes*) are destructive exotic mammal species (Atencio 1994. Proc. Sea Turtle Symp. 13:201–204; Bain et al., *op. cit.*; Drennen et al.

1989. Mar. Turt. Newsl. 1989:7–8; Engeman et al. 2003. Biol. Cons. 113:171–178; Foote et al. 2000. Proc. Sea Turtle Symp. 18:189–190; Helmstetter and Atencio 1997. Endangered Species Update 14:3–5; Lewis *et al.* 1996. Proc. Sea Turtle Symp. 15:162–164; Mroziak et al. 2000. Chel. Cons. Biol. 3:693–698; Rusenko et al. 2000. Proc. Sea Turtle Symp. 18:209–211; Woolard et al. Herpetol. Rev. *in press*; Wright et al. 2000. Proc. Sea Turtle Symp. 12:210–212). Here we provide the first observations of Bobcat (*Felis rufus*) acting as a primary predator (excavator) of marine turtle nests.

We have made observations since 1997 on the beach at Hobe Sound National Wildlife Refuge (HSNWR), Jupiter Island, Florida. HSNWR offers undeveloped and protected beach habitat for nesting by loggerhead (*Caretta caretta*), leatherback (*Dermochelys coriacea*), and green (*Chelonia mydas*) turtles, each of which is listed as threatened or endangered. Our first observation of bobcat excavation and predation of a turtle nest occurred in 2001. In that year 251 of the 1259 loggerhead nests, all 16 green turtle nests, and all 58 leatherback nests were marked for observation, for a total of 325 marked nests. On 10 September, a loggerhead nest was depredated by a bobcat. This was the only bobcat-predated nest during the 2001 nesting season, and it is the first observation of which we are aware where a bobcat excavated and predated the eggs of a marine turtle nest. The destruction of a single nest represented 0.4% of marked loggerhead nests and 0.3% of total marked nests for all marine turtle species.

In 2002, a total of 307 turtle nests were marked for observation; 132 of the 1062 loggerhead nests, all 142 green turtle nests, and all 33 leatherback nests. Two of the marked loggerhead nests were excavated and depredated by bobcats. This represented 1.5% of loggerhead nests and 0.7% of total marked nests on the refuge. Bobcat predation occurred on 29 and 30 July, which is when the maximal number of nests would be expected to be in this beach (e.g., Engeman et al., *op. cit.*).

Raccoons and armadillos are removed at HSNWR in an ongoing effort to protect turtle nests from these most destructive nest predators (Engeman et al., *op. cit.*). A predation rate around 1% by bobcats is negligible, especially when compared to depredation by raccoons and armadillos. While bobcat predation on turtle nests at its current level does not merit remediation, their populations and predation should be simultaneously monitored each year along with those for raccoons and armadillos in case their predation increases (for methodology see Engeman et al., *op. cit.*). On the other hand, if bobcat depredation remains at very low levels, then their presence on the beach may have the beneficial effect of deterring other, potentially more destructive, nest predators.

GOPHERUS POLYPHEMUS (Gopher Tortoise). **PREDATION.** *Gopherus polyphemus* is eaten by numerous native predators throughout its range (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington. 578 pp.). Here, we document a non-native reptile species, the Savannah Monitor (*Varanus exanthematicus*), preying upon a juvenile *G. polyphemus* in Florida.

On 22 September 2002, an adult male (37.3 cm SVL, 1.2 kg) *V. exanthematicus* was collected by residents at 1212 Alhambra Way S., St. Petersburg, Pinellas Co., Florida (27°43.39'N, 82°39.10'W), and brought to a staff member at nearby Boyd Hill Nature Park. On 24 September 2002, this *V. exanthematicus* defecated scutes and all four legs of a juvenile *G. polyphemus* (ca. 50 mm CL), as well as body parts of two adult ox beetles (*Strategus antaeus*). The *V. exanthematicus* and prey items were deposited in the Florida Museum of Natural History (UF 135537).

This *V. exanthematicus* was collected in a residential area ca. 335 m SSE of the largest remaining *G. polyphemus* population on the southern Pinellas County peninsula (pers. obs.). *Gopherus polyphemus* is a protected species throughout its range and is listed as a species of special concern in Florida (Moler 1992. Rare and Endangered Biota of Florida, Vol. III. Amphibians and Reptiles, Univ. Press of Florida, Gainesville, 291 pp.). Major threats to the Gopher Tortoise include habitat loss and degradation (Diemer 1986. Herpetologica 42:125–133), but heavy predation on *G. polyphemus* nests and juveniles is also a threat, due to the species' deferred sexual maturity and low fecundity (Diemer 1992. *In* Moler [ed.], Rare and Endangered Biota of Florida, Vol. III. Amphibians and Reptiles, Univ. Press of Florida, Gainesville, pp. 123–127).

Presently, more than 40 non-native herpetofaunal species are reported to be established in Florida (Townsend et al. 2003. Iguana 10:111–118), including three large lizards, the Mexican Black Spiny-tailed Iguana (*Ctenosaura pectinata*), Black Spiny-tailed Iguana (*C. similis*), and Nile Monitor (*Varanus niloticus*) (Campbell 2003. Iguana 10:119–120; Enge et al. 2004, unpubl.; Krysko et al. 2003. Florida Sci. 66:74–79; Townsend et al. 2003. Herpetozoa 16:67–72) that can potentially prey on *G. polyphemus*. Although there is presently no evidence that *V. exanthematicus* has established itself in Florida, this note documents the first predation of a protected reptile species in Florida by a non-native reptile species. Although it is illegal to release nonindigenous animals without a permit from the Florida Fish and Wildlife Conservation Commission (FWC), enforcement difficulties and inadequate regulatory control suggest that the release of non-native fauna will continue to be a major contributor to the state's battle with invasive non-native species.

We thank the collectors and Donna M. Heinrich (Boyd Hill Nature Park) for making the specimen available to us. We also thank Joan E. Berish, Kevin M. Enge, Paul E. Moler (Florida Fish and Wildlife Conservation Commission), and D. Bruce Means (Coastal Plains Institute and Land Conservancy) for helpful comments on this note. Michael C. Thomas (Entomology, Florida Division of Plant Industry) provided insect identification.

GOPHERUS POLYPHEMUS (Gopher Tortoise). **JUVENILE BURROW COHABITATION.** Hatchling and neonate chelonians have received little attention from field biologists (Morafka et al. 2000. Herpetol. Monogr. 14:353–370); thus most aspects of their ecology, including social behavior, are not well understood. In *Gopherus polyphemus*, adults often cohabit burrows with other conspecifics (see review in Smith et al. 1997. Chel. Cons. Biol. 2:358–362), or may usurp and enlarge burrows formerly inhabited by juveniles (Diemer 1992. J. Herpetol. 26:158–165); and juvenile tortoises occasionally occupy adult burrows (Douglass 1978. J. Herpetol. 12:413–415; Smith et al., *op. cit.*). Burrow sharing by juveniles has been previously reported (McRae et al. 1981. Am. Midl. Nat. 106:165–179; Diemer, *op cit.*); however, the authors make no reference to the sizes of the animals nor do they provide descriptions of the sharing events. Herein we provide the first descriptive documentation of burrow cohabitation involving two juveniles, as well as another event involving two sibling hatchlings at the Kennedy Space Center, Brevard County, Florida.

From 9 July–10 August 2003 a juvenile tortoise (Juvenile 1; carapace length = 9.8 cm) was monitored at a burrow (burrow width = 13.1 cm) using a motion-triggered digital camera. On 1 August 2003 at 1023 h a Peeper video camera system (Sandpiper Technologies, Manteca, California, USA) was also placed outside of the same burrow. Analysis of the videotape revealed another juvenile using the same burrow. The following is a description of the events recorded on the videotape. (Prior to this, Juvenile 1 was recorded entering the burrow on 30 July at 1431 h).

At 1053 h a juvenile tortoise (Juvenile 2; approximately the same CL as Juvenile 1, inferred from the videotape) walked directly up to the burrow and began digging at the entrance until it entered the burrow at 1054 h. At three separate times (from 1147–1150 h, 1154–1155 h, and 1255–1259 h) Juvenile 2 emerged from the burrow headfirst, turned around to face the entrance, and worked at enlarging it. Between these events it was inside the burrow. At 1504 h Juvenile 2 exited the burrow and was not seen again on the videotape.

At 1519 h on the same day an adult tortoise (> 25 cm CL) approached and attempted to force itself into the juvenile burrow. When the adult was unsuccessful, it turned around, briefly pulled inside its shell as if disturbed by an unknown source, and left the area at 1521 h.

At 1706 h a sand-covered Juvenile 1 emerged from the burrow, bit at some vegetation, began digging in the burrow entrance, and reentered the burrow at 1709 h. No further tortoise activity was observed on the videotape, which ended at 1833 h. Logistical constraints did not allow further videotaping of this burrow, and digital camera data did not reveal further co-occupation of juveniles within the burrow. Juvenile 1 left the burrow on 10 August 2003 and no tortoises have used it since.

At the same site, the burrow cohabitation of two hatchling tortoises hatched from the same nest (on 9 October 2003) was also observed. Both animals were given a unique mark and Hatchling 1 was outfitted with a radiotransmitter. Hatchling 1 was tracked daily from release until the present observation took place. During this time Hatchling 1 never dug a burrow, but instead used multiple short pallets. Hatchling 2 was recaptured on 8 March 2004 outside of its burrow (6.5 cm wide), fitted with a radiotransmitter, and released in the same location on 9 March. At the time we recaptured Hatchling 2 the tortoises were within 1.0 m of each other and both had dispersed 9.0 m from the nest since hatching.

After 9 March, Hatchling 2 was always in its burrow and Hatchling 1 was located 1.6 m away in its pallet. On 29 March Hatchling 1 was seen walking 1.8 m from the burrow of Hatchling 2. On 30 March both animals were found inside the burrow of Hatchling 2. Hatchling 2 was deeper inside the burrow and Hatchling 1 had about 20% of its body sticking out of the burrow. Over the next several days the tortoises remained in the same relative positions, but by 5 April both were completely inside the burrow. By 14 April Hatchling 2 had moved from the original burrow and dug another burrow 2.3 m away. Hatchling 1 was still using the original burrow.

Burrow takeover by tortoises has been reported elsewhere (Diemer, *op cit.*). Little is known about the significance of social interactions between immature turtles and tortoises and even less is known about sibling interactions. Research into the behavioral interactions of Gopher Tortoises and other species, especially juveniles and siblings, should be a focus of future research.

NASA at the Kennedy Space Center, the Dynamac Corporation, Merritt Island National Wildlife Refuge, and Canaveral National Seashore provided support.

LEPIDOCHELYS KEMPII (Kemp's Ridley Seaturtle). **DIET.** Dietary studies on post-pelagic *Lepidochelys kempii* document that crabs are a primary food source (Bjorndal 1997. *In* Lutz and Musik [eds.], The Biology of Sea Turtles, pp. 206–207. CRC Press, Boca Raton, Florida). Trawl fishery discards (fish or shrimp) may also be a supplemental food source in some regions. Portunid crabs are emphasized as a predominate prey item, but spider crabs, rock crabs, and lady crabs are also common in gut contents of live and stranded turtles. Here we report an attempted ingestion of a *Limulus polyphemus* (Horseshoe Crab) by a *L. kempii* in the Gulf of Mexico.

In September 2003, line transect surveys were conducted by the Sarasota Dolphin Research Program throughout Charlotte Harbor National Estuary along Florida's southwest coast. A survey on 8 Sept. encountered a *L. kempii* at 1329 h near the mouth of Alligator Creek (26.86555°N, -82.06394°W; depth 2.5 m, sandy-mud bottom adjacent to seagrasses composed of *Halodule*, *Syringodium*, and sparse *Thalassia*). The turtle swam at the surface with its head

elevated while holding a *Limulus polyphemus* in its jaws, grasped by the posterior margin, presumably to avoid the telson. A photo sequence recorded with a Nikon D100 6.1 MP digital camera illustrated lateral, frontal, and dorsal views while the turtle swam at the surface. The extreme dorsal flexion of the crab indicated that the crab was alive, verifying that the turtle was not scavenging a dead crab from the bottom. The turtle submerged briefly, lost its grip on the crab and when it resurfaced, shifted its mouth grasp of the prey item. It was impossible to follow the turtle or its prey to confirm ingestion of the crab. Estimates based on photo dimensions suggest that the ridley was a large subadult or adult, and the crab was of adult size (AAB, pers. obs.).

Limulus polyphemus is a common prey item of Loggerhead Turtles (*Caretta caretta*) in Virginia (Lutcavage and Musik 1985. Copeia 1985:449–456) but has been mentioned rarely in the diets of ridleys (Seney 2003. Master's thesis, College of William and Mary). *Limulus* is distributed geographically from the Yucatan peninsula to northern Maine with peak abundance in Delaware Bay (Botton and Ropes 1987. Fish. Bull. 84[4]:805–812).

We thank the Mote Scientific Foundation for support and facilities in Charlotte Harbor.

LEPIDOCHELYS KEMPII (Kemp's Ridley Seaturtle). **NEST ARCHITECTURE**. Studies describing sea turtle nest architecture have been largely limited to the Loggerhead Seaturtle (Carthy 1996. The Role of the Egg Shell and Nest Chamber in Loggerhead Turtles [*Caretta caretta*] Egg Incubation. Ph.D. dissertation. Univ. Florida, Gainesville. 123 pp.; Tiwari et al. 2003. Herpetol. Rev. 34:138–139). Here we report nest architecture data for the highly endangered Kemp's Ridley.

Data were collected from five nesting Kemp's Ridley seaturtles during the 2001 nesting season at Rancho Nuevo, Tamaulipas, Mexico. After recording standard size and clutch data, each turtle was removed from the nest after oviposition but prior to refilling. The eggs were removed, and the egg chamber cleaned of any loose sand and debris. A cast was made by filling the entire nest cavity with minimally expanding polyurethane construction foam and allowed to cure. Excess foam was cut off at the top of the nest structure flush with the surface of the sand and the cast excavated. A typical sea turtle nest is roughly urn-shaped, consisting of a narrow neck with a larger egg chamber at the bottom. The maximum diameters of the neck and egg chamber were measured as well as the distance from the top of the sand to the top and bottom of the egg chamber. Nest volumes were determined by measuring the amount of water displaced when the cast was submerged.

Mean carapace lengths (CCL) and weights of the five turtles were 69.8 cm (± 3.2) and 38.0 kg (± 2.9), and all five turtles were observed to have normal rear flippers. The mean number of eggs per nest was 96.4 (± 16.1). The mean depths from the top to the bottom of the nests were 21.6 cm (± 2.6) and 39.6 cm (± 3.6), and the mean diameters of the neck and egg chamber were 13.6 cm (± 1.7) and 28.0 cm (± 2.0), respectively. The mean nest volume was 6620 ml (± 2510).

FIG. 1. Polyurethane nest molds of the five Kemp's Ridley Seaturtles showing differences in size and shape.

The shapes and sizes of these nests varied considerably (Fig. 1). The shapes were probably influenced by the substrate in which the nests were constructed and the location on the beach. Substrate materials ranged from moist broken shell to dry rocky sand/soil. Variation in the dimensions of the nests, and resultant volumes, could also be attributed to the type of substrate, turtle size, and possibly the number of eggs deposited. There was a positive, but weak, correlation between the number of eggs per nest and nest volume ($r = 0.422$), while better relationships were found for turtle length and nest volume ($r = 0.835$), and turtle weight and nest volume ($r = 0.932$). Consequently, Kemp's Ridley nest sizes appear to be more of a function of turtle size and not clutch size, although a larger sample size would increase confidence in statistical analyses.

It is difficult to compare nest cast sizes with those previously done for Loggerheads because of different measuring techniques. However nest volumes for the Kemp's Ridleys and the Florida and Brazilian Loggerheads (Tiwari et al., *op. cit.*) averaged 6620 ml, 11030 ml, and 11757 ml, respectively. The much larger Loggerhead nest size undoubtedly reflects the equally large difference in mature sizes between Kemp's Ridleys (65 cm) and Loggerheads (90 cm), respectively (Marquez 1994. NOAA Tech. Memo. NMFS-SEFSC-343, 91 pp.; Dodd 1988. U.S. Fish Wildl. Serv. Biol. Rep. 88[14], 110 pp).

Conservation biologists at Rancho Nuevo currently relocate almost all nests to protected corrals, using a manual post-hole digger to excavate the main part of the nest. The egg chamber is then hand sculpted at the bottom of the hole and the eggs are then deposited and covered with sand. The depth of the relocated nests is currently 45 cm and the dimensions of the egg chambers are at the discretion of the individuals transplanting that particular nest. The five nests observed in this study ranged in depth from 38–45 cm (mean = 39.6). This is shallower than the standard 45 cm currently used in the corrals. Also, when hundreds of nests are being transplanted in a single day, the sizes of the egg chambers tend to be smaller than naturally occurs (pers. obs.). Perhaps the percent hatching success rate might increase from the present 55–65% by making the nest hole shallower and the egg chamber larger. However, a follow up study using a larger sample size should be undertaken before changes in the current conservation techniques are considered.

I thank P. Burchfield, L. J. Peña, and A. S. Quintero for field support.

PHRYNOPS GEOFFROANUS (Geoffroy's Side-necked Turtle). **DIET.** *Phrynops geoffroanus* has the widest geographical distribution among the South American freshwater turtle fauna, ranging from the Colombian Amazon to southern Brazil, Uruguay, and northern Argentina. This species occurs primarily in large streams and lakes, and appears to be tolerant of polluted waters (Vanzolini 1994. Smithson. Herpetol. Inf. Serv. 97:1–10). Despite this turtle's broad range, information on its natural diet is quite scarce. Some published data suggest that habitat characteristics might influence diet (Fachin-Teran et al. 1995. J. Herpetol. 29:536–547; Souza and Abe 2000. J. Zool. 252:437–446). We examined digestive tract contents (stomach flushing and feces) of 28 *P. geoffroanus* captured June–September 2003 in a dam reservoir at the upper Paraná River, bordering Mato Grosso do Sul and São Paulo States, Brazil (20°49'15"S, 51°39'31"W). Diet analyses are summarized in Table 1. *P. geoffroanus* from the sampled region exhibits predominantly carnivorous feeding habits, consuming fishes, crustaceans, mollusks, and insects. The presence of plant material in three stomachs (10.7%) may represent incidental ingestion.

We thank Universidade Federal de Mato Grosso do Sul for financial support.

Submitted by **LEONARDO CORNIANI DIAS**, Universidade Federal de Mato Grosso do Sul, Centro de Ciências Biológicas e da Saúde, Departamento de Biologia, 79070-900, Campo Grande, Mato Grosso do Sul, Brazil); and **FRANCO LEANDRO SOUZA**, Universidade Federal de Mato Grosso do Sul, Centro de Ciências Biológicas e da Saúde, Departamento de Biologia, 79070-900, Campo Grande, Mato Grosso do Sul, Brazil (e-mail: flsouza@nin.ufms.br).

PODOCNEMIS UNIFILIS (Yellow-spotted River Turtle). **NESTS** and **NESTING**. *Podocnemis unifilis* is widely distributed along the Amazon and Orinoco Basins in South America (Pritchard and Trebbau 1984. The Turtles of Venezuela. Society for the Study of Amphibians and Reptiles, Athens, Ohio, pp. 33–73). Like other species of *Podocnemis, P. unifilis* is of economic importance to the people who live in the region, due the high quality of its meat and eggs (Smith 1979. Acta Amazônica 9:87–97). Studies on this turtle's breeding biology were carried out in Colombia (Foote 1978. Herpetologica 34:333–339), Venezuela (Thorbjarnarson et al. 1993. J. Herpetol. 27:344–347; Escalona and Fa 1998. J. Zool. 244:303–312), but data are almost inexistent for Brazil (Thorbjarnarson and Silveira 1996. Herpetol. Rev. 27:77–78). From September to November 2000/2001 we collected data on nests of *P. unifilis* in Reserva Biológica do Rio Trombetas. The reserve has an area of 385,000 ha and is located in the northwest part of state of Pará, municipality of Oriximiná, on the northeast bank of Rio Trombetas (1°46'S, 55°52'W), Brazil. Nesting took place in the sandbanks (tabuleiros) formed by the dropping water levels and on lakeshore beaches. Observations and data were collected at Tabuleiro do Farias, Tabuleiro do Jacaré, and Lago do Jacaré.

Nests were excavated and the nest depth (measured vertically between surface and incubation chamber) and the distance between the entrance of the nest and the incubation chamber were measured with a metric tape. Eggs were measured in the early morning immediately after nesting using a caliper with precision of 0.05 mm and weighed to the nearest 1 g with Pesola spring scales. To avoid natural and human predation, eggs were transferred to permanently monitored areas in the same sandbank. Original position of eggs was established with a pencil mark on top of each egg.

Most nests were found at a distance of 3–780 m from the water on lake beaches; some were on sandbanks near or covered by vegetation, rarely in places totally exposed to the sun. The following data are based on 30 nests: mean total nest depth: 17.7 ± 2.7 cm; depth of the first egg in relation to the surface: 9.0 ± 3.3 cm; mean length of the incubation chamber: 18.4 ± 3.4 cm; width of the incubation chamber: 16.3 ± 2.3 cm; and diameter of nest mouth: 9.4 ± 1.3 cm. Clutch size (N = 37) varied from 7 to 27 eggs (mean = 19) in both years. Mean egg length was 4.4 cm (3.8–5.1 cm), mean egg width was 2.9 cm (2.4–3.2 cm), and mean egg mass, 22.5 g (15.0–30.0 g). Incubation periods varied from 58 to 66 days (mean = 61). In these two years of study, hatching was completed about one month before the beginning of the rainy season.

IBAMA provided the permit to work with *Podocnemis unifilis* at Reserva Biológica do Rio Trombetas - Brazil (IBAMA 02010.003215/00-44). This study was supported by FAPESP (Fundação de Amparo à Pesquisa do Estado de São Paulo), CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnológico) and Conservation International. Thanks to IBAMA (Rio Trombetas) for logistic support and to the following people for help in the field or laboratory: Flávio de Barros Molina, Márcio Martins, Alberto Guerreiro, and Renata Moretti.

PSAMMOBATES GEOMETRICUS (Geometric Tortoise). **DIET**. *Psammobates geometricus* is an endangered tortoise restricted to

renosterveld in the southwestern corner of South Africa. Twenty-four genera or species of plants have been reported as food for these tortoises, either by visual observation or fecal analysis (Baard 1990. Ph.D. dissertation, University of Stellenbosch, South Africa, 208 pp.). In one study, 40% of the plant epidermi examined in feces were unidentifiable (Baard, *op. cit.*), suggesting that many food plant species have yet to be catalogued.

On three consecutive days (13–15 October 2002), while researching *P. geometricus* at the Elandsberg Private Nature Reserve (Hermon, Western Cape Province, South Africa 33°24'S; 19°01'E), we observed three adult Geometric Tortoises feeding. A male tortoise fed on the leaves of *Cyanella hyacinthoides* (lady's hand), a monocotyledonous geophyte that has not been reported earlier as a food plant for *P. geometricus*. A female tortoise ate the leaves of another monocotyledonous geophyte, *Lachenalia contaminata* Aiton (wild hyacinth), also a new species for the *P. geometricus* diet list. This tortoise also ate leaves of *Cynodon dactylon* (quick grass), a low-lying grass previously reported as a food plant by Baard (*op. cit.*). Another female tortoise fed on leaves of *Cynodon dactylon* and the leaves and inflorescence of *Briza maxima* (quaking grass, 10–40 cm tall), a grass reported as food plants (Baard, *op. cit.*; Engelbrecht 1995. Ph.D. dissertation, University of Stellenbosch, South Africa. 176 pp.).

Renosterveld, a habitat once widespread in western South Africa, has been reduced by over 90% due to farming, development, and an altered fire regime (Parker 1982. Veld and Flora 68:98–101). These factors, as well as invasive plants and animals, continue to threaten the remaining renosterveld. Thus, to conserve *P. geometricus*, it is imperative that we identify and conserve their food plants. Our observations confirm previous reports that low-lying grasses are a component of the diet of this tortoise and also expand the *P. geometricus* database of native food plants by two species of monocotyledonous geophytes.

CROCODYLIA

ALLIGATOR MISSISSIPPIENSIS (American Alligator). **MORTALITY.** Alligators are large, long-lived carnivores (Campbell 2003. Appl. Herpetol. 1:45–163) and non-human causes of mortality (besides cannibalism; Rootes and Chabreck 1993. Herpetologica 49:99–107) are rarely reported. Anthropogenic factors are more commonly reported as causes of alligator deaths, which include direct take (Mazzotti and Brandt 1994. *In* Davis and Ogden [eds.], Everglades: The Ecosystem and its Restoration, pp. 485–505. St. Lucie Press, Delray Beach, Florida), road mortality (Smith and Dodd 2003. Florida Sci. 66:128–140), toxicants caused by pollution (Schoeb et al. 2002. J. Wildl. Dis. 38:320–337), or bacterial infections that a variety of human-influenced or environmental factors may aggravate (Clippinger et al. 2000. J. Zoo Wildl. Med. 31:303–314). Besides road mortality (Smith and Dodd, *op cit.*) and cannibalism (Rootes and Chabreck, *op cit.*), this report is the first documentation of an American Alligator dying because of presumptive behavioral error.

On 31 July 2003, we observed a large (3.6 m) dead American Alligator of undetermined sex on the bank of the Banana River at the Merritt Island National Wildlife Refuge, Brevard County, Florida (28°34'56"N, 80°36'45"W; elev. 1 m; Fig. 1). The alligator was facing away from water lying perpendicular to the bank on a 45° slope and a well-used emergence trail was located ca. 1 m W of the animal. The alligator was pinned between 4 large limestone rocks (Fig. 1). The forelimbs were outstretched with the anterior rocks extending from the axial region down to mid-body. Each hind leg was also hemmed in by a rock on either side of the pelvic region. The rocks were all sufficiently large (the smallest next to the left leg measured 40 x 52 x 33 cm) and heavy that an adult human could not move them without difficulty.

At the time of discovery scavengers had chewed off the hands and feet and the skin had begun to crack open in several places, exposing the flesh, implying the carcass was several days old. Examination of the cracked skin showed no indication that these lesions represented human-inflicted wounds (including gunshot) and later re-examination of the skull failed to show evidence of trauma. The location of this find is within a secure, remote area of the Kennedy Space Center (where weapons are not permitted) with restricted access.

FIG. 1. American Alligator (*Alligator mississippiensis*) found stuck between rocks along the Banana River, Brevard County, Florida.

We believe that the alligator became inextricably trapped between these rocks while climbing up the steep bank and could not escape due to the bank angle and the awkward positioning of the alligator. Alligators normally use an upright high-walk posture when moving overland, where the limbs are erect underneath the body and move parallel to the body axis (Pough et al. 2001. Herpetology. Prentice Hall, New Jersey. 612 pp.). Rocks enclosing the axial region of the body causing the headward extension of the forelimbs may have prevented the alligator from effectively positioning the limbs underneath the body. Crocodilians can also use a sprawling posture during locomotion to travel short distances or to make the transition from a resting position to a high-walk (Reilly and Elias 1998. J. Exp. Biol. 201:2559–2574), but this type of locomotion requires the limbs to be outstretched perpendicular to the body, an option that may not have been possible here.

We thank NASA at the Kennedy Space Center, the Dynamac Corporation, Towson University, and Merritt Island National Wildlife Refuge for support. Joseph C. Mitchell, Marc P. Hayes, and two anonymous reviewers provided helpful comments on an earlier draft.

LACERTILIA

AMEIVA AMEIVA (Calango Verde). **COURTSHIP BEHAVIOR.** *Ameiva ameiva*, a heliothermic teiid widely distributed in Central and South America, is abundant in ecotonal areas and typically active during prolonged sunlight intervals (Colli 1991. Copeia 1991:1002–1012; Sartorius et al. 1999. Biol. Cons. 1999:91–101; Zaluar and Rocha 2000. Ciência e Cultura 52:101–107). Despite this abundance and broad distribution, most aspects of courtship and reproduction remain unknown for most populations of this species. Herein, we describe courtship behavior in *A. ameiva* from southeastern Brazil.

Our observations were made on a lawn on the grounds of the Serra do Cipó National Park headquarters (19°00'S, 43°40'W; elev. 515 m) on 22 October 2001 at 1500 h. We encountered an adult male *A. ameiva* following an adult female and making ca. 80-cm diam circles around her while she kept moving forwards. After at least three attempts to intercept her over a one-minute period, the female stopped and the male clasped her by mounting her back, and wrapping his tail around hers on her left side. The male seized the female by her hind legs using his forelimbs and kept making circular movements with his tail. Copulation could not be directly observed from our position, but the pair remained in the same position for 30 sec; during that time, the female was passive and the male's tail kept moving. Subsequently, the female broke free from the male, and moved away. When she had move away a distance of ca. 0.5 m, the female encountered an adult treefrog, *Scinax fuscovarius*, in the shade. After three attempts to capture it, the female caught the frog by its hind limbs as it tried to escape. The treefrog vocalized twice, emitting a scream before being killed by head shaking. During this time, the male *A. ameiva* had remained behind the female. The male continued to follow the female with the treefrog in her mouth. When the male got too close, the female tried to flee, alternatively running and walking away. We saw the female enter and exit a drainpipe several times. When the male arrived, the female emerged. Sometimes, the female would briefly deposit the treefrog on the ground but as the male approached, the female would retrieve it and run away. We discontinued observations after 25–30 min as no obvious changes had occurred in the pair's behavior.

We thank Pedro Amaral Oliveira for contribution during the observations; Edeltrudes Maria Valadares Calaça Câmara e Leonardo Oliveira, who permitted one of the authors (FM) to participate in the field work for the Mastozoology Project at Serra do Cipó National Park; Ronaldo Fernandes, Marcelo Soares, and Marc P. Hayes, for offering helpful suggestions on the previous versions of the manuscript; and IBAMA for providing logistic support.

EUPREPIS ATLANTICUS (Noronha Skink). **PREDATION.** This lizard, formerly known as *Mabuya maculata* or *M. punctata*, is endemic to the Fernando de Noronha Archipelago off NE Brazil (Mausfeld and Vrcibradic 2002. J. Herpetol. 36:292–295; Mausfeld et al. 2002. Zool. Anz. 241:281–293). It occurs across habitats from rocky seashore to insular forest, and thrives on a broad range of foods ranging flower nectar to human leftovers (IS, pers. obs.). No snakes or raptorial birds exist on the archipelago; thus, the Noronha Skink likely evolved without native predators. Humans tolerate the skink as well; all houses harbor sizeable populations (up to 29 animals have been counted in a six-room dwelling; IS, pers. obs.). However, human colonization of the archipelago has brought three rodent pests—Brown Rats (*Rattus rattus*), Norway Rats (*Rattus norvegicus*), and House Mice (*Mus musculus*)—as well as Domestic Cats (*Felis catus*) and Domestic Dogs (*Canis domesticus*). A few pairs of the giant tegu (*Tupinambis merianae*) were introduced in the 1950s for the alleged purpose of controlling rats and giant toads (*Bufo paracnemis*), the latter of which also represents an introduction. Additionally, the Cattle Egret, already present in the 1980s, established breeding colonies in the archipelago by the year 2000 (JSM, pers. obs.). Herein, we report on predators of the Noronha skink as well as record cannibalism by this lizard (Table 1).

Except for the predation records by tegus, which we obtained from examination of gut contents, most records were direct visual observations. We obtained visual records opportunistically from June 2000 to January 2003, whereas tegu diet was studied from March 2000 to October 2001. Cats and egrets always stalked the skinks, whereas the tegu chased its prey—a hunting tactic it employs for smaller lizards (Sazima and Haddad 1992. *In* Morellato [ed.], História Natural da Serra do Japi, pp. 221–236. Edunicamp, Campinas). In the cannibalistic encounters, *E. atlanticus* adults robbed eggs from within shallow oviposition burrows of conspe-

TABLE 1. Predation records on the Noronha Skink (*Euprepis atlanticus*).

Predators	N	Comments
Felis catus	23	Kittens killed, but did not eat 2 skinks
Mus musculus	1	Potential scavenging
Rattus norvegicus	2	
Rattus rattus	1	
Bubulcus ibis	11	
Tupinambis merianae	5	Actual predation event recorded once
Euprepis atlanticus	5	Eggs (2); juveniles (2); adult tail (1)

cifics, or chased smaller individuals often consuming their tail after a brief aggressive encounter. Cannibalism is recorded for the continental skink *Mabuya frenata* (Vrcibradic and Rocha 1996. Herpetol. Rev. 27:201–202) and occurrence of this habit in *E. atlanticus* may be related both to its well-developed opportunistic foraging behavior and high population densities (pers. obs.). One rat was found eating its prey during the day, but most probably took *E. atlanticus* in its nocturnal retreats. In all instances of consumption by rodents, the skink was already dead when the event was recorded, so it is unclear how frequently scavenging rather than actual predation occurs. As the House Mouse was similar in size to the skink, a greater likelihood exists that consumption by mice involves scavenging. We lack definitive data to support the view that any of the predators may be causing skink populations to decline on the archipelago. However, we noted that houses with resident cats have few or no skinks in their neighborhoods. A cat which gave birth to four kittens weaned them with skinks, and we recorded eight skinks preyed on by this adult and seven others by its kittens. Additionally, the toll taken by Cattle Egrets also may be high, as we recorded a single egret catching three skinks in a row during a foraging bout of about 10 min.

Submitted by **JOSÉ MARTINS SILVA-JR.,** Centro Golfinho Rotador, CP 49, 53990-000 Fernando de Noronha, Pernambuco, Brazil; **AYRTON KLIER PÉRES-JR.,** Departamento de Zoologia, Universidade de Brasília, 70910-900 Brasília, DF, Brazil; and **IVAN SAZIMA**, Departamento de Zoologia and Museu de História Natural, CP 6109, Universidade Estadual de Campinas, 13083-970 Campinas, São Paulo, Brazil (e-mail: isazima@unicamp.br).

MICROLOPHUS PERUVIANUS (NCN). **CANNIBALISM**. Cannibalism is common among reptiles, with many cases reported among lizards (Polis and Myers 1985. J. Herpetol. 19:99–107; Mitchell 1986. SSAR Herpetol. Circ. 15:1–37). Two cases involve species of *Microlophus* (formerly included in *Tropidurus*; Mitchell, *op. cit.*), but *M. peruvianus* is not among them. Here, I report an observation of cannibalism in *M. peruvianus* from northern Peru.

On 25 July 1997, I observed an adult male *M. peruvianus* ingesting a live conspecific juvenile in Lobos de Tierra Island, Departamento de Lambayeque (06°28´S, 80°50´W; elev. 15 m). The adult was moving while carrying the juvenile in its mouth. After 2 min, the adult stopped and ingested the juvenile using lateral movements of its head. I could only see the dorsum, posterior limbs and tail of the juvenile. I was unable to capture the adult male, but I could identify the juvenile because of its characteristic yellow-orange inguinal markings (Dixon and Wright 1975. Nat. Hist. Mus. Los Angeles Co. Contrib. Sci. 271:1–39) which are not present in conspecific adults nor in any other sympatric lizards species.

Microlophus peruvianus was introduced to Lobos de Tierra Island to control ectoparasites that affect guano bird populations (Vogt 1942. Bol. Cia. Admora. Guano 18:1–132). Whether it exerts such an effect is unconfirmed, but *M. peruvianus* is the only known tick consumer at this locality and in similar habitat on other islands (Perez and Jahncke 1998. Bol. Inst. Mar del Peru 17:81–86; Duffy 1983. Ecology 64:110–119). *Microlophus peruvianus* and *Phyllodactylus microphylus* are the only lizards known from Lobos de Tierra Island, and appear to have densities that are higher than those observed on the mainland. This condition may increase the likelihood of cannibalism (Polis and Meyers, *op. cit.*).

I am grateful to Javier Icochea and Joseph Mitchell for suggestions to this manuscript.

Submitted by **JOSE PEREZ Z.**, Departamento de Herpetología, Museo de Historia Natural de la Universidad Nacional Mayor de San Marcos, Apartado Postal 140434, Lima – 14, PERU; e-mail: perezz_jm@hotmail.com.

MICROLOPHUS THERESIAE (NCN). **SAUROPHAGY**. Members of the lizard genus *Microlophus* are mostly insectivores (Dixon and Wright 1975. Contrib. Sci. Nat. Hist. Mus. Los Angeles Co. 271:1–39). Predation by Peruvian desert *Microlophus* on other sympatric lizards is unreported. Here, we report saurophagy by *M. theresiae* from central Peru.

At 1230 h on 10 April 2001, we captured an active adult male *M. theresiae* (65.8 mm SVL, 8.0 g., MHNSM 18600) in the Reserva Nacional de Lachay, Departamento de Lima (11°20'48"S, 77°19'45"W; elev. 180 m). The stomach of the *M. theresiae* contained two juveniles of *M. thoracicus* (ca. 22 mm SVL, 0.4 g, MHNSM 18601; ca. 27 mm SVL, 0.8 g, MHNSM 18602), which were the only foods items in the stomach. Given the parallel degree of digestion, both lizards were probably eaten in the same day. The three individuals were deposited in the Herpetology Collection of the Department of the Museo de Historia Natural de la Universidad Nacional Mayor de San Marcos, Lima, Peru.

The site of this observation is part of the Peruvian desert, characterized by sandy substrate, few rocks of different sizes, and little vegetation. This habitat is typical for adults of *M. theresiae* and juveniles of *M. thoracicus*. Overlap in microhabitat use and activity (both species are diurnal) increases their likelihood of encounter despite their apparently relatively low densities. Moreover, our observation of saurophagy coincided with the dry season when the availability of arthropods is low.

We thank Carlos Frederico D. Rocha for comments and improvements on the manuscript.

PEDIOPLANIS LINEOOCELLATA (Spotted Sand Lizard). **ENDOPARASITES.** *Pedioplanis lineocellata* is a lacertid lizard that occurs in the western half of the African subcontinent but is absent from regions of deep sand, e.g., Namib desert and central Kalahari (Branch 1998. Field Guide to Snakes and other Reptiles of Southern Africa. Ralph Curtis Books, Sanibel Island, Florida. 399 pp.). Goldberg and Bursey (2002. Afr. Zool. 37:159–164) reported one species of Cestoda (*Oochoristica ubelakeri*) and four species of Nematoda (*Maxvachonia dimorpha, Spauligodon smithi, Thubunaea fitzsimonsi,* as well as ascarid larvae) in *P. lineoocellata* from Botswana. The purpose of this note is to report a second species of Cestoda in *P. lineoocellata.*

During an examination of coelomic cavities of 535 *P. lineoocellata* from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA, three adult cestodes were found in LACM 79142 (60 mm SVL); two adult cestodes were found in LACM 84087 (64 mm SVL). These cestodes were regressively stained in hematoxylin, mounted in Canada balsam on glass slides and identified as *Oochoristica truncata.* Voucher cestodes were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland as USNPC 94424.

Four species of *Oochoristica*, namely, *O. theileri, O. truncata, O. ubelakeri,* and *O. zonuri*, have been reported in South African lizards (Bursey et al. 1994. Trans. Am. Microsc. Soc. 113:400–405). These species exhibit little host specificity. *Oochoristica truncata*, the most frequently reported taxon, is known from the lizard families Agamidae, Chamaeleonidae, Cordylidae, Gekkonidae, Scincidae as well as the snake families Boidae and Colubridae (Goldberg and Bursey 2004. Afr. Zool. 39:111–114). *Pedioplanis lineoocellata* is the second South African lizard reported to harbor two species of *Oochoristica. Agama hispida* has been previously reported to harbor both *O. theileri* and *O. truncata* (Malan 1939. Onderstepoort J. Vet. Sci. An. Husb. 12:21–74; Simbotwe 1979. Afr. J. Ecol. 17:177–180). *Oochoristica truncata* in *P. lineoocellata* is a new host record.

BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

PHRYNOSOMA ASIO (Giant Horned Lizard). **COPULATION POSITION**. Lizards in the genus *Phrynosoma* normally copulate following sometimes extensive visual and olfactory displays when a male assumes a position on the female's back (Baur and Montanucci 1998. Krötenechsen, Herpeton, Verlag Elke Köhler, Offenbach, 158 pp.; Sherbrooke 2003. Introduction to Horned Lizards of North America, University of California Press, Berkeley. 176 pp.). The male maintains this position by using his jaws to bite and grip skin on the female's neck or nuchal fold, or by biting her occipital or temporal horns. The place used by the male to secure his jaw hold varies within and between species, with short-horned species preferring a neck skin hold (Baur and Montanucci, *op. cit.*). The male uses all four legs to assist in maintaining his straddle position. Thus situated, the male wraps his tail to the side of the female's tail and endeavors to bring his cloaca into contact with the female's cloaca, ideally with her cooperation in positioning, prior to the male inserting one of his hemipenes into the female's cloaca for insemination. In the coast horned lizard, *P. coronatum*, the male has been reported to utilize a dramatically different position for copulation, one possibly unique to amniotes except humans (Wood 1936. Copeia 3:177; Lynn 1963. Ph.D. dissertation, University of Oklahoma, Norman. 75 pp.; Montanucci 1968. Herpetologica 24:316-320; Tollestrup 1981. Herpetologica 37:130–141; Montanucci and O'Brien 1991. Vivarium 3:27–28). The male grasps the female in his jaws by her neck or gular skin and, with a quick jerk, flips the female onto her back. Then he secures a position on top of the female that brings them into belly-to-belly contact (see photographs in Montanucci and O'Brien, *op. cit.*; Baur and Montanucci, *op. cit.*). The male retains his jaw hold on the female's gular skin and spreads his legs to maintain an upright position on top of the inverted female. He then positions his lower abdomen and tail to bring their cloacas into contact and inserts a hemipenis for copulation. Although this position has been observed numerous times it is not always used, with males of this species being seen to mount females for copulation in the male-on-female's back position (Tollesrup, *op. cit.*; Baur and Montanucci, *op. cit.*) more widespread among horned lizards. Males of the giant horned lizard, *P. asio*, are also reported to use the typical male-on-female's back copulatory position, holding the female's neck skin in their jaws (see photographs in Baur 1979. Salamandra 15:1–12; Baur and Montanucci, *op. cit.*). Davis and Dixon (1961. Proc. Biol. Soc. Washington 74:37–56) reported observing a mating sequence in the field but did not comment on copulatory position, suggesting that it was not unusual (i.e., belly-to-belly). Here, we report four field observations of mating position in *P. asio* in which the male was positioned over the inverted female with his belly oppressed to her belly while holding her gular skin in his jaws. These represent the first observations of this unique belly-to-belly mating position being used by any species of lizard other than *P. coronatum*.

Between 1998 and 2003, one of us (EBS) and students from the Universidad Autónoma de Guerrero conducted field investigations on *P. asio* and *P. taurus* at Cerro Tepetlayo (17°83'09"N, 99°31'31"W; elev. 1280 m), Zumpango del Río, Municipio de Eduardo Neri, Guerrero, México. The following observations were made on four mating pairs of *P. asio*, all utilizing the belly-to-belly copulatory position for mating. On 1 June 1999, a 50-g female (95 mm SVL, 49 mm tail) was found copulating with a 56-g male (100 mm SVL, 71 mm tail; Fig. 1). The mating was observed for ca. 15 min before the two animals separated and departed. On 9 June 1999, a male and female were seen to approach each other with the female raising her tail and wagging it from side to side. No vent licking (Sherbrooke 1988. Ph.D. dissertation, University of Arizona, Tucson, 202 pp.) was observed. The male grabbed the female by the neck skin in his jaws, threw her onto her back, and then moved over her so that they were in a belly-to-belly position. He held her for 6 min before she escaped his hold. He followed her, but then seemed to lose interest and walked away. Copulation was not observed. A third pair was observed on 6 June 2001. When encountered at 1030 h the male was following the female. Observations lasted 1.5 h. The male turned the female over onto her back after securing a jaw hold on her

FIG. 1. Male and female *Phrynosoma asio* in belly-to-belly copulatory position.

under the neck and assumed a belly-to-belly position on top of her. He wrapped his tail around her tail before introducing his hemipenis for copulation. A fourth pair of giant horned lizards were found copulating about 15 days later in June 2001. The pair was mating in a belly-to-belly position when encountered, and the male's everted hemipenis was seen as the pair separated. In three of the four field observations of belly-to-belly mating behavior, copulation was observed. The absence of the typical *Phrynosoma* mating posture (except in *P. coronatum*) during these field observations of *P. asio* is noteworthy. Also of interest, all matings occurred in June, a timing parallel to the 26 June field observation near Chilpancingo (Davis and Dixon, *op. cit.*), and to a captive mating on 24 June (Baur, *op. cit.*). The mating dates recorded here agree with the typical time for oviparous species of horned lizards, May-July (Zamudio and Parra-Olea 2000. Copeia 2000:222–229).

Observations of a belly-to-belly copulatory position in *P. asio* bring to two the number of species in the genus exhibiting this mating posture. Whether these positional differences within species are attributable to pairs in particular encounters, individual behaviors, or population characteristics is unknown. Both *P. asio* and *P. coronatum* potentially represent the least derived taxa in the two evolutionary branches of the genus, the northern and southern radiations (Montanucci 1987. Contri. Sci. Nat. Hist. Mus. Los Angeles Co. 390:1–36; Zamudio et al. 1997. Syst. Biol. 46:284–305). Thus, whether lack of reports of this mating behavior in other species is due to its evolutionary loss, insufficient observations of matings, or other factors is unclear. Functional aspects of this unusual lizard mating posture remain elusive, but are intriguing. The position may aid the male in his attempts at maintaining a firm grip on the female, whose locomotion is severely restricted while inverted. In this position, the male is not subject to injury from the female's horns during copulations, which might not always involve the full cooperation of the female. In *P. asio*, the occipital horns are notably erect and positioned adjacent to particularly long, and posteriorly-projecting, supraocular spines. In *P. solare*, a well-armored species with extra cranial horns, males apparently avoid the bite-holding of horns or neck skin during copulation, maintaining position solely with their legs (Baur and Montanucci, *op. cit.*). Cranial horn thrusts are known to be capable of inflicting serious wounds in male-to-male combat (Whitford and Whitford 1973. Herpetologica 29:191–192). *Phrynosoma asio* also has the longest, most erect, and most impressive array of dorsal spines on its back of any species of horned lizard; these structures may impose additional obstacles to a male attempting to mount and copulate successfully with a female that is typically larger in size than the male (Zamudio 1998. Evolution 52:1821–1833). Compared to females that mate with males who secure horns during copulation (Lynn, *op. cit.*), females in belly-to-belly copulations may experience reduced horn breakage.

Among horned lizards, social signals involving head bobbing, push-ups, vent flashing, vent licking, and attempted mounting provide individuals with opportunities to visually and chemically assess species identity, sex, reproductive status, and receptivity of other congeners (Tollestrup, op. cit.; Montanucci and Baur 1982, Copeia 1982:971–974; Sherbrooke 1988, 2003, *op. cit.*). A male's attempt to mount a female is near the terminal end of this sequence. In non-territorial horned lizards (Stamps 1977. *In* Gans and Tinkle [eds.], Vol. 7, Biology of the Reptilia, pp. 265–333. Academic Press, London.; Munger 1984. Oecologia 62:351–360), males can have difficulties encountering suitable sexual partners due to low population densities, restricted visual landscapes (Stamps, *op. cit.*; Sherbrooke 2002. Herpetol. Rev. 33:21–24), or brief seasonal sexual receptivity of females (Munger 1984, *op. cit*; Sherbrooke 2002, *op. cit.*). Availability of multiple methods to secure an advantageous copulatory position may enhance male fitness. The belly-to-belly mating position may allow easier introduction of the male's copulatory organ, a potential advantage with reluctant females.

We thank B. Roth for assistance with translation of papers written in German, B. Baur for manuscript review, L. Milroy for discussion of unpublished observations of belly-to-belly matings in *P. coronatum*, and students from the Universidad Autónoma de Guerrero for help in the field.

PHRYNOSOMA BRACONNIERI (Short-tail Horned Lizard). **DEFENSIVE BEHAVIOR**. Sherbrooke and Middendorf (2001. Copeia 2001:1114–1122) recently noted that all members of the genus *Phrynosoma* do not seem to utilize the ability to eject blood from ocular sinuses with the same frequency. Some species (*P. mcallii*, *P. modestum*, and *P. platyrhinos*) apparently are "non-blood-squirting" based on: 1) an extremely low frequency (0.07%) of squirting during field encounters with humans, compared to 5.9% with *P. cornutum* (Lambert and Ferguson 1985. Southwest. Nat. 30:616–617), and 2) experimental trials with a canid model, dogs (*Canis familiaris*), in which no blood squirting was observed in trials with all three species (N = 11, 10, and 15, respectively). Moreover, the three non-blood-squirting species may represent a

clade (Sherbrooke and Middendorf, *op. cit.*). For other species in the genus, particularly poorly known taxa in Mexico (*P. braconnieri*, *P. ditmarsi*, and *P. taurus*), available data were insufficient for a determination of the occurrence or frequency of blood squirting. Preliminary data on *P. ditmarsi* from trials with a dog (Sherbrooke and Middendorf, *op. cit.*; Hodges, Southwest. Nat., *in press*; W. L. Hodges, pers. comm.) suggest that this species uses blood squirting as an anti-predator defense, but its frequency of use remains unclear. A recent reevaluation of blood squirting in *P. taurus* (Sherbrooke et al. 2004 Herpetol. Rev. 35:345–347), involving field encounters by humans and trials with a canid model (dog), suggests that *P. taurus* may be a non-blood-squirting species (*contra* Ruthling 1919. Copeia 72:67–68). This new evidence of non-blood-squirting status for *P. taurus* suggested that reevaluation of its apparent sister taxon, *P. braconnieri*, was in order. Here, we use field encounters and trial observations of *P. braconnieri* to evaluate its blood-squirting status, which remains unreported (Sherbrooke and Middendorf, *op. cit.*).

Five *Phrynosoma braconnieri* were collected in xerophytic vegetation on 20–21 June 2003, ca. 5 km NE San Juan Tepango de López, Puebla, México (18°35'16"N, 97°32'38"W; elev. 1800 m). No lizard squirted blood when encountered, picked up, and placed in a cloth bag. Two were adult females (59 and 63 mm SVL) and three were juveniles (34, 37, and 39 mm SVL). We included juvenile *P. braconnieri* because juvenile *P. cornutum* and *P. hernandesi* squirt blood (Sherbrooke and Middendorf, *op. cit.*), and juvenile *P. braconnieri* might also display the behavior if this species squirts blood. Each lizard was tested in late afternoon on the day of capture with a canid model predator, a German Shepherd-mix dog. Air temperature was 20°C (20 June), and light rain fell before and after the five 3-min trials. During trials, the dog barked and vigorously tried to paw and mouth the lizards. Due to the size and strength of the dog, it was restrained on a leash to prevent injury to the lizards. Test lizards frequently ran from the dog, requiring recapture and return to the test area. Nevertheless, the lizards were presented with close (20 cm) visual, auditory, and chemical (saliva) cues from the dog, and tactile stimuli from the paws. Tactile stimulation of being picked up in the jaws of the surrogate predator was lacking. The person handling the lizards (WCS) had extensive experience with similar trials (Sherbrooke and Middendorf, *op. cit.*).

Throughout the trials, the lizards' eyelids remained open and unswollen, with one exception. Following one trial (37 mm juvenile), the lizard's eyelids became "puffy" (fide Middendorf and Sherbrooke 1992. Copeia 1992:519–527) during handling by the experimenter, indicating a change in blood pressure in the ocular sinuses. Tactile stroking of the eyelids (2 min) in a fashion similar to that use to obtain blood squirting in *P. cornutum* (Sherbrooke and Middendorf, *op. cit.*) resulted in their enlargement (stage two fide Middendorf and Sherbrooke, *op. cit.*), but no blood squirting was seen.

For human field encounters, our sample of five lizards, plus Hodges' six encounters, all lacking blood squirting events, support the hypothesis that *P. braconnieri* may be a non-blood-squirting species. Further, our five trials of *P. braconnieri* with a surrogate predator failed to elicit blood squirting. In similar trials with other species, the percentage of trials in which a positive response, blood squirting, was elicited were 70–100%, 50%, and 60%, with *P. cornutum* (N = 55), *P. hernandesi* (N = 6), and *P. solare* (N = 5), respectively (Middendorf and Sherbrooke, *op cit.*; Sherbrooke and Middendorf, *op. cit.*). This suggests that *P. braconnieri* is less likely to squirt blood in response to a canid predator threat than are these latter species. The likelihood of using this defense in *P. braconnieri* may be similar to that of *P. taurus*, where it seems low or absent (Sherbrooke et al. 2004, *op. cit.*). Given our re-evaluation of *P. taurus* as a possible non-blood-squirting species, and the preliminary data presented here, we suggest that the use of a blood-squirting defense by *P. braconnieri* remains incompletely understood. Sherbrooke and Middendorf (*op. cit.*) speculated that *P. braconnieri* may be a blood-squirting species; that evaluation now seems premature.

We thank Ada Molleda Contreras for assistance in the field and for generously providing us with accommodations and access to the use of a family dog (Kiara) for behavioral trials. Wendy L. Hodges generously provided access to her unpublished manuscript. Animal care and handling procedures were approved by the IACUC of the American Museum of Natural History, and collection of lizards by FMQ was facilitated by the INE.

UMA EXSUL **(Coahuila Fringe-toed Sand Lizard). BODY TEMPERATURE.** Relatively little ecological information exists about *U. exsul*, a Chihuahuan Province endemic (Norma Ecologica Mexicana, NOM-059-ECOL-2001. Diario Oficial de la Federación. 2002. México, D.F., México. 77 pp.) considered at risk of extinction (Gadsden et al. 2001. Bol. Soc. Herpetol. Mex. 9[2]:51–66) because of low genetic variability and agricultural development fragmenting populations. Here, we provide preliminary body temperature data on this species.

During a 1997–1999 population study near the municipality of Viesca, Coahuila, Mexico, we obtained body temperature data on *U. exsul* from two dune areas, Saucillo (25°26'23"N, 102°55'23"W; elev. 1100 m) and Gabino Vazquez (25°28'09"N, 103°02'09"W; elev. 1100 m), separated by a distance of ca. 10 km. Dune vegetation is almost entirely perennial shrubs: Creosote Bush (*Larrea tridentata*), Black Seepweed (*Suaeda nigrescens*), and Honey Mesquite (*Prosopis glandulosa*). We conducted 15 days of fieldwork in May and August between 1000 and 1300 h. Individuals of *U. exsul* were captured with a noose or by hand on a 2-ha plot in each study area. We obtained body temperatures only from lizards captured almost immediately after they were sighted. We also did not obtain body temperatures on lizards that ran more than 5 m before capture. Each lizard was permanently marked by toe-clipping and also given a temporary dorsal acetate mark that could be seen easily so as to prevent recapture of individuals on the same day. Gravid females were excluded from this analysis since too few were captured. One body temperature (T_b; to 0.1°C) was obtained for each lizard with a rapid-reading cloacal thermometer on each day. Data were taken within 10 sec of capture to avoid changes in T_b that

might result from manipulation. Gender was identified by the presence of large postanal scales or everted hemipenes in males. We measured SVL (to the nearest mm) using a flexible ruler and body weight (W; to the nearest 0.1 g) with a Pesola™ spring scale. Lizards were released at the point of initial sighting following processing. A Kolmogorov-Smirnov goodness of fit test revealed SVL, weight, and temperature to be normality distributed, so we used t-tests to compare means of SVL, body weight, and T_b between females and males. We assumed all tests to be significant at $\alpha = 0.05$; measurements are reported as mean ± SE.

We found no significant differences in T_b between Saucillo and Gabino Vazquez populations, so the data were pooled ($t = 1.22$, df = 202, $P > 0.05$). Mean SVL for females was 63.7 ± 0.5 mm (N = 108; range = 49–83 mm) and 78.5 ± 0.5 mm (N = 96; range = 45–100 mm) for males. The mean W of females was 8.3 ± 0.2 g (N = 108; range = 3–12 g) and 12.5 ± 0.1 g (N = 96; range = 3–25.5 g) for males. Females were significantly smaller than males in length ($t = 7.38$, df = 202, $P < 0.05$) and body weight ($t = 2.4$, df = 202, $P < 0.05$). The mean T_b for females (34.3 ± 0.2°C) and males (35.5 ± 0.4°C) was not significantly different ($t = 0.71$, df = 202, $P > 0.05$); T_b for both sexes pooled was 35 ± 0.1° C (N = 204, range = 31.5–40.0°C). The mean T_b of *U. exsul* was slightly lower than values reported for the other *Uma*. The T_b for *U. inornata* is 38°C (Mayhew 1964. Herpetologica 20:95–113), for *U. notata* is 37.8°C (Turner and Schwalbe 1998. Final Report. Arizona Game and Fish Department Heritage Fund. IIPAM Project No. I95042. 78 pp.), and Licht and Basn (1967. Nature 213:672–674) reported 37.5°C for *U. scoparia* (experimentally tested). On the contrary, *U. paraphygas*, the smallest species in the genus, has a mean body temperature of 34.26 ± 0.18°C (García-de la Peña, unpubl. data). *Uma inornata*, *U. notata*, and *U. scoparia* are more closely related to each other than *U. exsul* and *U. paraphygas*, and vice versa, so the similarity in preferred temperature among each of these groups of species may be a function of phylogeny. However, behavioral experiments and controlled cross-species comparisons will be required to address alternate hypotheses.

We thank Gamaliel Castañeda-Gaytán, Ulises Romero-Méndez, and Anselmo Orona-Espino for their valuable help in the field, and Marc P. Hayes for suggestions on the manuscript. This study was supported by CONACYT (1367-N9206) and CONABIO (L173).

SERPENTES

AGKISTRODON PISCIVORUS (Cottonmouth). **DIET**. On 23 May 1995, at ca. 1730 h, one of us (GY) observed and 15 minutes later photographed a Cottonmouth attempting to ingest, by the right forelimb, the carcass of a Domestic Cat (*Felis catus*) killed by a car the previous evening, and which was lying at the bottom of a slope adjacent to a road in Marion County, Mississippi, USA. Most authors consider *A. piscivorus* to be a generalist feeder known to ingest carrion (Gloyd and Conant 1992. Snakes of the *Agkistrodon* Complex. SSAR, Oxford, Ohio; Hamel 1996. J. Herpetol. 27:143; Heinrich 1996. J. Herpetol. 27:22), but this is the first record, to our knowledge, of this species attempting to scavenge on a Domestic Cat. The snake released the carcass and moved into nearby underbrush because of the activities of the photographer.

ARIZONA ELEGANS ARENICOLA (Texas Glossy Snake). **DIET.** Medium-sized diurnal lizards comprise a large proportion of the diet of *Arizona elegans* (Rodríguez-Robles et al. 1999. J. Herpetol. 33:87–92). Rodríguez-Robles et al. (*op. cit.*) suggest that diurnal lizards may be captured "when they are inactive by nocturnally wide-foraging glossy snakes." Here, we record several observations of diurnal foraging by *A. elegans* among sand dunes near the municipality of Viesca, Coahuila, Mexico (ca. 70 km SE of Torreon). On 3 April 2002 at 1030 h, an *A. elegans arenicola* was observed consuming an *Aspidoscelis marmoratus* (ca. 78 mm SVL) beneath a Desert Seepweed (*Suaeda nigrescens*) plant. On 13 July 2002 at 1230 h, a second *A. e. arenicola* (670 mm SVL) was observed preying upon an *A. marmoratus* (ca. 80 mm SVL) that had been foraging beneath Creosote Bush (*Larrea tridentata*), Honey Mesquite (*Prosopis glandulosa*), and Desert Seepweed. The snake constricted the lizard for ca. 8 minutes and took 38 minutes to ingest it. We thank Adriana Jaime R. for field assistance.

BOTHROPS NEUWIEDI PAULOENSIS (Jararaca Rabo-de-osso). **PREDATION**. Records of predation on neotropical snakes are scarce. The only documented record of predation on *Bothrops neuwiedi* reports the consumption of this snake by the burrowing owl *Speotyto* (*Athene*) *cunicularia* (Valdujo and Nogueira 2000. Herpetol. Rev. 31:45). Here, I report predation on *Bothrops neuwiedi pauloensis* by the Little Water Opossum, *Lutreolina crassicaudata* (Mammalia: Didelphidae). The observation occurred on 3 November 1999 at 1600 h in Emas National Park (18°06'S, 52°55'W), municipality of Mineiros, Goiás, Brazil. The snake and the opossum were fighting under the thick grass layer at the edge of a road and rolled to the open area of the road. The pitviper was

coiled on the opossum and the mammal tried to bite the snake. After some seconds, both returned to the grass and I could only hear them. The snake, with several bites on the head and body, emerged from the grass, trying to flee, but the opossum bit the snake again and pulled it. Next, I observed the opossum carrying the dead serpent. *Lutreolina crassicaudata* and *Didelphis albiventris* (both members of the Didelphidae) are reported to prey on other pitviper species, *Bothrops jararaca* (Sazima 1992. Biology of the Pitvipers, pp. 199–216). The venom of pitvipers is very active for most mammals, but some opossum species, including *L. crassicaudata*, have an anti-bothropic protein complex in the serum fraction of their blood (Perales et al. 1986. An. Acad. Bras. Ciênc. 58:155–162; Perales et al. 1994. Toxicon 32:1237–1249; Farah et al. 1996. Toxicon 34:1067–1071), which presumably confers a degree of resistance to pitviper venom.

BUNGARUS FLAVICEPS (Red-headed Krait). **VERTICAL DISTRIBUTION**. *Bungarus flaviceps* is a conspicuous elapid snake distributed from southern Vietnam to the Malay Peninsula and on the islands of Sumatra, Nias, Bangka, Belitung, and Borneo (Kuch and Schneyer 1996. Sauria 18:3–16). Two subspecies are currently recognized. *Bungarus flaviceps baluensis* was long considered an endemic of Mount Kinabalu in northern Borneo but is more widely distributed on that island and may deserve recognition as a separate species (Kuch 2002. Herpetozoa 14:149–151; Kuch and Götzke 2000. Sauria 22:19–22). The nominate subspecies occurs throughout the remainder of the range (Brongersma 1948. Zool. Mededelingen 30:1–29). Although the known vertical distribution of *B. f. baluensis* extends from 1550 m to as low as 550 m (Kuch and Götzke, *op. cit.*), that of *B. f. flaviceps* has been known to range from sea level (near the coast of Perak, Malaysia; Tweedie 1983. The Snakes of Malaya. Singapore, Singapore National Printers, 167 pp.) to ca. 600 m (in the Nakhon Si Thammarat Mountains, Thailand; Smith 1930. Bull. Raffles Mus. 3:1–149).

Here we report a subadult *B. f. flaviceps* of undetermined sex (683 mm SVL, 67 g; MVZ 241564) collected by J. A. McGuire and Humberto Wong at 2050 h on 22 November 1997 in primary or mature secondary forest along the road between Gunung Hijau Resthouse and Telkom Station, near the summit of Bukit Larut (Perak, Malaysia) at ca. 1200 m elevation. The present record suggests that the vertical distribution of some populations of *B. f. flaviceps* may overlap that of *B. f. baluensis* (0–1200 m vs. 550–1550 m, respectively). Additional collecting efforts are required to better elucidate geographic and vertical distribution in Borneo, where both forms may occur in parapatry or sympatry.

We thank the Unit Perancang Ekonomi, Malaysia, the National Geographic Society, and Kiew Bong Heang for support and assistance.

Submitted by **JIMMY A. McGUIRE**, Museum of Vertebrate Zoology, 3101 Valley Life Science Building, University of California, Berkeley, California 94720-3160, USA (e-mail: mcguirej@socrates.berkeley.edu); **ULRICH KUCH**, Sektion Herpetologie, Forschungsinstitut und Naturmuseum Senckenberg, Senckenberganlage 25, 60325 Frankfurt am Main, Germany (e-mail: U.Kuch@em.uni-frankfurt.de).

CROTALUS MITCHELLII STEPHENSI (Panamint Rattlesnake). **DIET**. Very few literature records exist on the diet of *Crotalus mitchellii stephensi*. Klauber (1972. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. Univ. California Press, Berkeley. 1533 pp.) reviewed diet in this taxon and reported stomach contents to include small mammals (*Dipodomys*, *Perognathus*, and *Citellus*) and lizards (*Callisaurus draconoides* and *Cnemidophorus tigris*). Cox and Tanner (1995. Snakes of Utah. Brigham Young Univ. Press, Provo. 92 pp.) report that *C. m. pyrrhus* opportunistically preyed on "lizards" from can traps at the Nevada Test Site in southern Nevada (this is probably a record for *C. m. stephensi*, as *C. m. pyrrhus* is not known to occur at the site). Here, I report on the stomach contents of an adult male *C. m. stephensi* (LACM 36696; 781 mm SVL) collected by Lester Northern on 20 June 1967 from the Deep Springs Valley, Inyo County, California. Upon dissection, I found the snake to contain the partially digested remains of a Desert Horned Lizard (*Phrynosoma platyrhinos*) and a passerine bird tentatively identified as a Thrasher (*Toxostoma* sp.). Both prey items had been ingested headfirst, with the *P. platyrhinos* situated posteriorly in the alimentary tract. The head and most of the neck were completely missing from the bird. Birds have been reported from the diet of *C. m. pyrrhus* (Klauber 1936. Trans. San Diego Soc. Nat. Hist. 8:149–184; Klauber, *op. cit.*), but not, to my knowledge, from *C. m. stephensi*. Although Lowe et al. (1986. The Venomous Reptiles of Arizona. Arizona Game and Fish Department, Phoenix. 116 pp.) included "desert horned lizards" as prey of *C. mitchellii*, specific data were not provided and the context of the statement suggests predation in captivity. To my knowledge, this is the first record of *C. m. stephensi* predation on *Phrynosoma*. I thank Kent Beaman for permission to examine specimens.

CROTALUS WILLARDI OBSCURUS (New Mexico Ridge-nosed Rattlesnake). **FORAGING.** On 10 July 1996 we surgically implanted a male *Crotalus willardi obscurus* (507 mm SVL, 100 g) from the Animas Mountains (New Mexico, USA) with a 2.4 g radio-transmitter (helical antennae) and located him daily until 30 November. At 1130 h on 22 October 1996 he was found at ca. 2300 m elevation with a *Sceloporus jarrovii* in his mouth, which he proceeded to consume headfirst. Air temperature 1 m above the ground was 6.8°C and substrate temperature was 30.5°C. On 25 October 2003 we captured an adult female *C. w. obscurus* (457 mm SVL, 93.6 g) at an elevation of 1915 m in the Sierra San Luis (Sonora, Mexico). She contained a recent food bolus consistent in size, shape, and feel with a medium-sized lizard. On 13 September 2003 we surgically implanted a 5.2 g radio-transmitter in an adult female *C. w. obscurus* (531 mm SVL, 123.1 g) from the

Sierra San Luis (Chihuahua, Mexico). At 1358 h on 14 December 2003 we found her on a NE-facing slope among oak and manzanita chaparral (1908 m elev.). She was last located on 3 November at a distance ca. 100 m away. She lay in an S-shaped ambush posture 3 cm beneath a 10-cm diameter downed log in complete shade and 25 cm from a patch of snow. Her head overlooked a 2-cm diameter branch. When disturbed she rapidly retreated to a burrow entrance 30 cm away. Ten cm of snow had accumulated at this site on 11 and 12 December, but on 13 and 14 December clear and sunny conditions and highs of ca. 10°C resulted in significant snowmelt. Seven other radio-tagged *C. w. obscurus* were below ground when located on 13 and 14 December.

Our observations of 1) consumption of lizards, including *S. jarrovii,* and 2) ambush posture among fallen branches and logs, are consistent with previous descriptions of foraging biology in *C. willardi* (Holycross et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 243–252. Eagle Mountain Publishing, Eagle Mountain, Utah). Our observations demonstrate that *C. w. obscurus* not only intermittently bask at low air temperatures (*see also* Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. University of New Mexico Press, Albuquerque, New Mexico. 431 pp.), but feed late into fall and perhaps in winter. We thank Rocky Mountain Research Station, U.S. Forest Service for funding.

LEPTOPHIS NEBULOSUS (Oliver's Parrot Snake). **REPRODUCTION.** *Leptophis nebulosus* is a colubrid that occurs from extreme northeastern Honduras throughout Costa Rica (Savage 2002. The Amphibians and Reptiles of Costa Rica; A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago. 934 pp.). There is no information on clutch sizes in *L. nebulosus*. Here I present information on a single clutch from a specimen from Costa Rica.

One *L. nebulosus* (LACM 151850) collected May–June 1982 in Puntarenas Province, measured 710 mm SVL, contained eight enlarged ovarian follicles (mean length = 18.1 mm ± 1.4 SD, range = 16.8–20.1 mm). The eggs are deposited in the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

MASTICOPHIS FLAGELLUM (Coachwhip). **DIET.** *Masticophis flagellum* is known to take a large variety of prey items including insects, lizards, snakes, small turtles, birds and their eggs and rodents (e. g., Stebbins 1985. A field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 336 pp.). Here we report predation on Curve-billed Thrasher (*Toxostoma curvirostre*) chicks. On 28 June 2003 in the San Juan y Puentes conservation area, near Aramberri (Nuevo León, México) we observed two Curve-billed Thrasher chicks in a nest perched in a Tree Cholla (*Opuntia imbricata*). At 1132 h the same day we returned to find a *M. flagellum* (ca. 1300 mm TL) on top of the nest with a Curve-billed Thrasher chick in its mouth. The second chick was missing, presumably already consumed by the snake. The startled Coachwhip dropped the chick and escaped into a nearby kangaroo rat burrow. We extracted the snake for measurement and it promptly regurgitated the chick it had ingested.

Submitted by **DAVID LAZCANO** (e-mail: dvlazcano@hotmail.com), **CHRISTINA GARCIA-DE LA PEÑA, GAMALIEL CASTAÑEDA G., ARMANDO J. CONTRERAS-BALDERAS, J. ARNOLDO SÁNCHEZ-ALMAZÁN,** and **OSCAR BALLESTEROS-MEDRANO,** Laboratorio de Herpetología, Universidad Autónoma de Nuevo León. Apartado Postal 513, San Nicolás de los Garza, Nuevo León, C.P. 66450, México.

MICRURUS BALIOCORYPHUS (NCN). **DIET.** Little is known of the natural history of *Micrurus baliocoryphus*, and much of this is conjecture based on the biology of sympatric congeners. Members of the genus *Micrurus* are best known for their consumption of other snakes although amphisbaenians, caecilians, and lizards occasionally are recorded as prey (Cei 1993. Reptiles del Noroeste, Nordeste y Este de la Argentina. Mus. Reg. Scien. Natur. Torino, Monogr. XIV, Turin. 949 pp.; Schouten 1931. Rev. Soc. Cien. Paraguay 3:5–32). To our knowledge, this is the first record of a fish being consumed by a *Micrurus* in South America. At 1600 h on 10 November 1999 we found a dead male *M. baliocoryphus* (463 mm SVL, 502 mm TL) ca. 2 km W of National Route 9 "Carlos A. Lopez," on the way to Fortín General Díaz (Department of Presidente Hayes, Paraguay). The specimen (MNHNP 5143) was collected and an anguilliform fish *Synbranchus marmoratus* (209 mm TL) was found in the stomach upon dissection. The snake was found a few meters from an artificial pool on the side of the road among Chacoan Xerophytic Forest. The presence of fish in the diet of *M. baliocoryphus* suggests that it may be semi-aquatic, as has been observed for some other members of the genus (Pérez 1999. Serpientes de Panamá. Biosfera, UNESCO, Gráf. San Antonio, Sevilla. 312 pp.). The specimen is deposited in the Museo Nacional de Historia Natural del Paraguay and is also cited in Da Silva and Sites (1999. Herpetol. Monogr. 13:142–194). We thank Darío Mandelburguer for help identifying the fish.

Submited by **EMILIO BUONGERMINI PALUMBO,** Proyecto Paraguay Silvestre, Secretaría del Ambiente, Madame Lynch 3500, Asunción, Paraguay (e-mail: subtropy@conexion.com.py); and **PIER CACCIALI,** Museo Nacional de Historia Natural, Sucursal 1, Ciudad Universitaria, San Lorenzo, Paraguay, (e-mail: pier_cacciali@yahoo.com).

NERODIA ERYTHROGASTER NEGLECTA (Copper-bellied Watersnake). **FORAGING BEHAVIOR**. The foraging ecology of aquatic and semi-aquatic snakes has received much investigation. However, observations of prey capture are rare, with most studies of foraging ecology based on dissection of museum specimens or regurgitations of captured snakes, both of which offer limited information on the locations where snakes actually encountered prey. Here we report predatory behavior by *Nerodia erythrogaster neglecta* at substantial distances from water in northwestern Ohio, USA. The first instance occurred on 27 July 2001 at 1200 h. A radio-tagged male *N. e. neglecta* (750 mm SVL, 251 g) was followed into the upland forest where it was observed to encounter, capture, and attempt to swallow an adult *Bufo americanus*. The toad avoided being swallowed by inflating its body. On 29 July 2002 at 1330 h, a second radio-tagged male *N. e. neglecta* (760 mm SVL, 267 g) was located in a small temporary wetland that had been dry for two months. The snake was probing dry leaf litter when it encountered, captured, and successfully swallowed an adult *B. americanus*. Both observations of terrestrial foraging occurred in late summer, when temporary wetlands had dried and most toads were likely in terrestrial habitats. The nearest wetlands containing surface water were 75 and 90 m away from these locations. Whether these snakes were actively hunting or had opportunistically encountered prey is uncertain, because *N. e. neglecta* frequently travels through terrestrial habitats between isolated wetlands (Roe et al. 2003. Wetlands 23:1003–1014). To our knowledge, these are the first reported observations of terrestrial foraging by *Nerodia*.

MYERS**, Department of Bioscience, Drexel University, Philadelphia, Pennsylvania 19104, USA (e-mail: mam322@drexel.edu).

OXYBELIS AENEUS (Brown Vine Snake). **REPRODUCTION.** *Oxybelis aeneus* is a colubrid that occurs from extreme southern Arizona to southeastern Brazil (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, 3rd Ed., Houghton Mifflin Company, Boston, 533 pp.). Information on clutch sizes is summarized by Goldberg (1998. Texas J. Sci. 50:51–56). Data on reproduction in populations from Arizona and Mexico is in Goldberg (*op cit.*) and Censky and McCoy (1988. Biotropica 20:326–333). Previously reported clutches ranged from 3–6 (Goldberg, *op. cit.*). Here I present information on clutch sizes of *O. aeneus* from Costa Rica.

Three gravid female *O. aeneus* were examined from the herpetology collection of the Natural History Museum of Los Angeles County (LACM). One female (LACM 153902) collected in April from Cartago Province, 710 mm SVL, contained four oviductal eggs (mean length 26 mm ± 1.6 SD, range: 25–28 mm). The second female (LACM 153934) collected in August from Puntarenas Province, 785 mm SVL, contained four enlarged ovarian follicles (mean length 20 mm ± 4.5 SD, range: 13–24 mm). The third female (LACM 153925) collected in July from Puntarenas Province, 680 mm SVL, contained two enlarged ovarian follicles that were close to ovulating (mean length 28 mm ± 2.5 SD, range: 26–30 mm). This clutch of two eggs represents a new minimum clutch size for *O. aeneus*.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

OXYBELIS BREVIROSTRIS (Cope's Vine Snake). **REPRODUCTION.** *Oxybelis brevirostris* is a colubrid that ranges from eastern Honduras to western Ecuador (Savage 2002. The Amphibians and Reptiles of Costa Rica; A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago. 934 pp.). There is one report of a *O. brevirostris* with three oviductal eggs (Guyer and Donnelly, unpubl. ms.). Here I present information on three egg clutches from *O. brevirostris* from Costa Rica.

A female *O. brevirostris* (LACM 153887, 642 mm SVL) collected in Limón Province on 8 June contained three oviductal eggs (mean length = 22.6 mm ± 2.2 SD, range = 21–25 mm). A second female (LACM 153888, 605 mm SVL) collected in Heredia Province on 2 April contained two enlarged ovarian follicles (mean length =15.6 mm ± 0.4 SD, range = 15.3–15.8 mm). A third (LACM 153885, 613 mm SVL) female collected in Heredia Province on 28 March contained two oviductal eggs (mean length = 20.4 mm ± 1.2 SD, range = 20–21 mm). Two eggs represents a minimum clutch size for *O. brevirostris*. Eggs are deposited in the Natural History Museum of Los Angeles County (LACM).

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail; sgoldberg@whittier.edu.

PHYLLORHYNCHUS DECURTATUS (Spotted Leaf-nosed Snake). **PREDATOR-PREY INTERACTIONS**. On 5 September 2002, 2115 h MST we collected a freshly hit and nearly dead male *Lampropeltis getula* (CAS 228326; 480 mm SVL, 36 g) on State Highway 238, Maricopa Co., Arizona, USA. The *L. getula* had a recently consumed an adult female *Phyllorhynchus decurtatus* (CAS 228327; 290 mm SVL, 15.3 g) in its stomach (orientation within the stomach was not noted); the *P. decurtatus* was completely intact, with no evidence of digestion. This is the first record of a Spotted Leaf-nosed Snake (*P. decurtatus*) in the diet of *L. getula* (Kevin D. Wiseman and Harry W. Greene, pers. comm.). In addition, the *P. decurtatus* had in its stomach an opened, but undigested, squamate eggshell, one end of which was missing (length 19.45 mm; estimated length including missing end 23.3 mm); the shell contained remnants of egg contents. September records of *P. decurtatus* in the Sonoran Desert are relatively rare, and of those, none had prey in their digestive tracts (Gardner and Mendelson 2003. Southwest. Nat. 48:550–556).

Submitted by **THOMAS R. JONES** (e-mail: trjones@gcu.edu) and **ROBERT H. HEGNA**, Department of Biology, Grand Canyon University, 3300 West Camelback Road, Phoenix, Arizona 85017, USA.

RHABDOPHIS MURUDENSIS (Gunung Murud Keelback). **DIET.** Little is known of the diet or natural history of *Rhabdophis murudensis* (reviewed by Stuebing and Inger 1999. A Field Guide to the Snakes of Borneo. Natural History Publications [Borneo] Sdn Bhd., Kota Kinabalu. 254 pp.). Stuebing and Tan (2002. Raffles Bull. Zool. 50:227–230) mention that captives of this natricine have been maintained on a diet of frogs (*Limnonectes kuhlii*) and occasionally white mice (presumably albinistic *Rattus rattus*).

An adult female *R. murudensis* (USDZ 2.5991; 738 mm SVL; head width 18 mm) collected 5 May 2003 on the ridge leading from Tukap Murud to Batu Linanit (03°55'N; 115°31'E, elev. 2200 m), Gunung Murud, Limbang Division, Northeast Sarawak, Malaysia (Borneo), regurgitated a recently-ingested adult megophryid frog (*Megophrys* sp.; ID-7779) with a head width of 34.5 mm and an SVL of ca. 79 mm. Although the condition of the frog (swallowed vent first) precluded specific identification, several traits suggest it is allied with *M. kobayashii*, a Gunung Kinabalu endemic (Malkmus et al. 2002. Amphibians & Reptiles of Mount Kinabalu [North Borneo], A. R. G. Gantner Verlag K.G., Ruggell. 424 pp.), from which it differs in lacking dermal projections at angle of jaws, paired conical tubercles on forehead, parallel rows of dark spots on abdomen, and by the presence of a dark dorsal saddle-like marking and a pale patch anterior to a dark interorbital bar. The systematic status of *M. kobayashii* is currently under study. The snake also regurgitated a large nematode (78 mm TL). All three specimens are deposited with the Zoological Museum of Universiti Malaysia Sarawak, Kota Samarahan, Sarawak, Malaysia.

For assistance and support we thank Fatimah Abang, the Institute of Biodiversity and Environmental Conservation (Universiti Malaysia Sarawak), and the Sarawak Biodiversity Centre. Financial support was provided by an Intensification of Research in Priority Areas Grant (number: 08-02-09-10007-EA0001) from the Federal Government of Malaysia.

Submitted by **INDRANEIL DAS** (e-mail: idas@ibec.unimas.my) and **ANDREW ALEK TUEN** (e-mail: aatuen@ibec.unimas.my), Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak, 94300, Kota Samarahan, Sarawak, Malaysia.

SAPHENOPHIS BOURSIERI (NCN). **HABITAT, REPRODUCTION and DIET**. *Saphenophis boursieri* is a neotropical snake known from the western slopes of the Andes (elev. 1100–1890 m) in Ecuador and southern Colombia, with disjunct records on the Amazonian lowlands of eastern Ecuador (Myers 1973. Amer. Mus. Novitates 2522). The genus *Saphenophis* is poorly represented in scientific collections (Myers, *op. cit.*; pers. obs.), and almost nothing is known of the natural history of any species of this genus. Myers (1969. Amer. Mus. Novitates 2385; *op. cit.*) reported "at least four large oviductal eggs, one (revealed by dissection) measuring 9 by 23 mm" in the paratype of *Saphenophis sneiderni* (394 mm SVL), and "large eggs in the oviducts" in the holotype of *Saphenophis antioquensis* (ca. 506 mm SVL). A specimen of *Saphenophis tristriatus* found "between 11 and 12 A.M… was lying in the sun on a wood bridge." Unfortunately, none of the specimens had collection dates. Herein I provide novel data on habitat, reproduction, and diet for *S. boursieri*.

Two female *S. boursieri* (DFCH-USFQ 701-702) were collected from the "Río Guajalito" protected forest (78°49'W, 0°14'S, elev. 1900 m), at the beginning of the dry season in June 2001 at 1400 h. This private reserve is located 59 km W of Quito among montane cloud forest on the northwestern slope of the Andes in Pichincha Province, Ecuador. One of the snakes (DFCH-USFQ 701) was found lying motionless upon sunlit leaf litter in the bottom of a dry ditch, ca. 5 m from the river and 25 m from human habitations. The other specimen (DFCH-USFQ 702) was found on the forest floor near a small trail, ca. 40 m from the river and 100 m from human habitations. Both females were gravid. Dissection revealed that DFCH-USFQ 701 (467 mm SVL, mass without eggs of 43.3 g) had five soft-shelled eggs that had a mean length of 30.4 mm (range 28.0–31.8 mm), mean width of 11.9 mm (range 10.1–13.0 mm), mean mass of 2.6 g (range 2.3–3.3 g, total clutch mass = 12.9 g), and a mean volume of 2.3 cm^3 (range 1.7–2.8 cm^3). The second female (DFCH-USFQ 702; 410 mm SVL) contained five immature ovarian eggs, the largest was 16.2 mm in length. Another female (FHGO-USFQ 003; 610 mm SVL) collected in April 1996 at San Antonio, Imbabura Province (near Ibarra, 78°09'W, 00°20'S, elev. 2500 m) contained seven unshelled oviductal eggs. Eggs had a mean length of 24.2 mm (range 15.7–29.6 mm). The stomach of one specimen (DFCH-USFQ 701) contained a larval hymenopteran and an orthopteran nymph (volume of both items = 0.2 cm^3). The other specimen (DFCH-USFQ 702) contained a partially digested gymnophthalmid lizard, *Proctoporus* cf. *unicolor* (volume = 0.6 cm^3). These observations of *S. boursieri* support Myers' hypothesis (1973, *op. cit.*) that snakes of the genus *Saphenophis* are principally diurnal. Moreover, *Saphenophis* seem to be essentially terrestrial and feed on a variety of prey from invertebrates to lizards.The three females and eggs are deposited at the Laboratorio de Anfibios y Reptiles, Universidad San Francisco de Quito.

I am grateful to Andres Leon, Kelly Swing, Maria Elena Heredia, Laura Heredia, and Vlastimil Zak for assistance, access to study sites, and financial support. This is contribution No. 4 of the Laboratorio de Anfibios & Reptiles FHGO-USFQ, Universidad San Francisco de Quito.

Submitted by **DIEGO F. CISNEROS-HEREDIA**, Laboratorio de Anfibios & Reptiles, Universidad San Francisco de Quito, Avenida Interoceanica y calle Diego de Robles, Campus Cumbaya, Edificio Maxwell, P.O. Box 17-12-841, Quito, Ecuador; e-mail: diegofrancisco_cisneros@yahoo.com.

THAMNODYNASTES STRIGATUS (NCN). **DIET**. Snakes are important predators of anurans, particularly in the tropics where anuran diversity is high. Species of *Thamnodynastes* are frequently cited as predators of adult anurans (Bernarde et al. 2000. Rev. Brasil. Biol. 60:695–699; Ruffato et al. 2003. Phyllomedusa 2:27–34). On 23 March 2004 at ca. 1530 h, we collected a *Thamnodynastes strigatus* (Museu de Ciências Naturais PUC Minas, MCNR 987, 220 mm SVL) foraging in a forest stream at Serra do Caraça, Minas Gerais State, Brazil. Upon dissection, a partially digested *Crossodactylus* cf. *bokermanni* (16.8 mm SVL, tibia 8.3 mm) was found in its stomach. SVL was estimated through correlative morphometric comparisons of tibia and SVL measurements with specimens of *Crossodactylus* cf. *bokermanni*. On 26

March 2004 at 1120 h, another *T. strigatus* (MCNR 988, 219 mm SVL) was captured on the edge of the same stream within 60 cm of two calling male *Crossodactylus* cf. *bokermanni* (SVL 23.8 and 22.0 mm). *Thamnodynastes* are primarily nocturnal, as are the majority of anurans that comprise their diet (Bernarde et al., *op. cit.*; Marques et al. 2001. Serpentes da Mata Atlântica. Guia Ilustrado para a Serra do Mar, Ribeirão Preto. Holos. 184 pp; Rufatto et al., *op. cit*). This is the first record *T. strigatus* preying on a diurnal anuran.

Submitted by **KATIA KOPP** (e-mail: kakopp@hotmail.com) and **MILENA WACHLEVSKI** (e-mail: milenawm@yahoo.com), Laboratório de Ecologia Evolutiva de Anfíbios e Répteis, Programa de Pós Graduação em Zoologia de Vertebrados, Pontifícia Universidade Católica de Minas Gerais, 30535-610, Belo Horizonte, Minas Gerais, Brazil.

TRIMERESURUS ALBOLABRIS (White-lipped Pitviper). **RESTING SITE.** Although *Trimeresurus albolabris* is occasionally found hunting on the ground at night, most accounts report that it is predominantly arboreal (Cox 1991. The Snakes of Thailand and their Husbandry. Krieger Publishing Company, Malabar. 526 pp.; Cox et al. 1998. A Photographic Guide to Snakes and other Reptiles of Thailand and Southeast Asia. Asia Books, Bangkok. 144 pp.; Das 2002. A Photographic Guide to Snakes and other Reptiles of India. New Holland Publishers, London. 144 pp.). Our own encounters have been primarily with individuals in trees and bushes, although several individuals were encountered moving on the ground at night (CAS 210108, 210665, 210690, 210691). Cox et al. (*op. cit.*) mention that during the day *T. albolabris* is typically found at rest in vegetation. On 13 April 2002 at 1609 h, one of us (HW) unearthed a male *T. albolabris* (625 mm SVL, 85 g; CAS 224646) near Nagmung Town, Kachin State, Myanmar (27°30'36.5"N, 97°49'50.4"E, WGS 84) at 613 m elev. The snake was inactive ca. 25 cm below ground level inside a termite mound located near a trail in an agricultural area in the midst of subtropical evergreen forest. This is the first record of any *Trimeresurus* using a termite mound as a retreat. We thank U Khin Maung Zaw, Alan Leviton, Jens Vindum, and the National Science Foundation (DEB-9971861).

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother 2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. SSAR Herpetol. Circ. 29:1–82, available online at <http://herplit.com/SSAR/circulars/HC29/Crother.html>; for Mexico as it appears in Liner 1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*. Herpetol. Circ. 23:1–113), LOCALITY (use metric for distances and give precise locality data), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author—curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Leviton et al. 1985. *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology*, Copeia 1985[3]:802–832) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief), SUBMITTED BY (give name and address in full—spell out state or province names—no abbreviations).

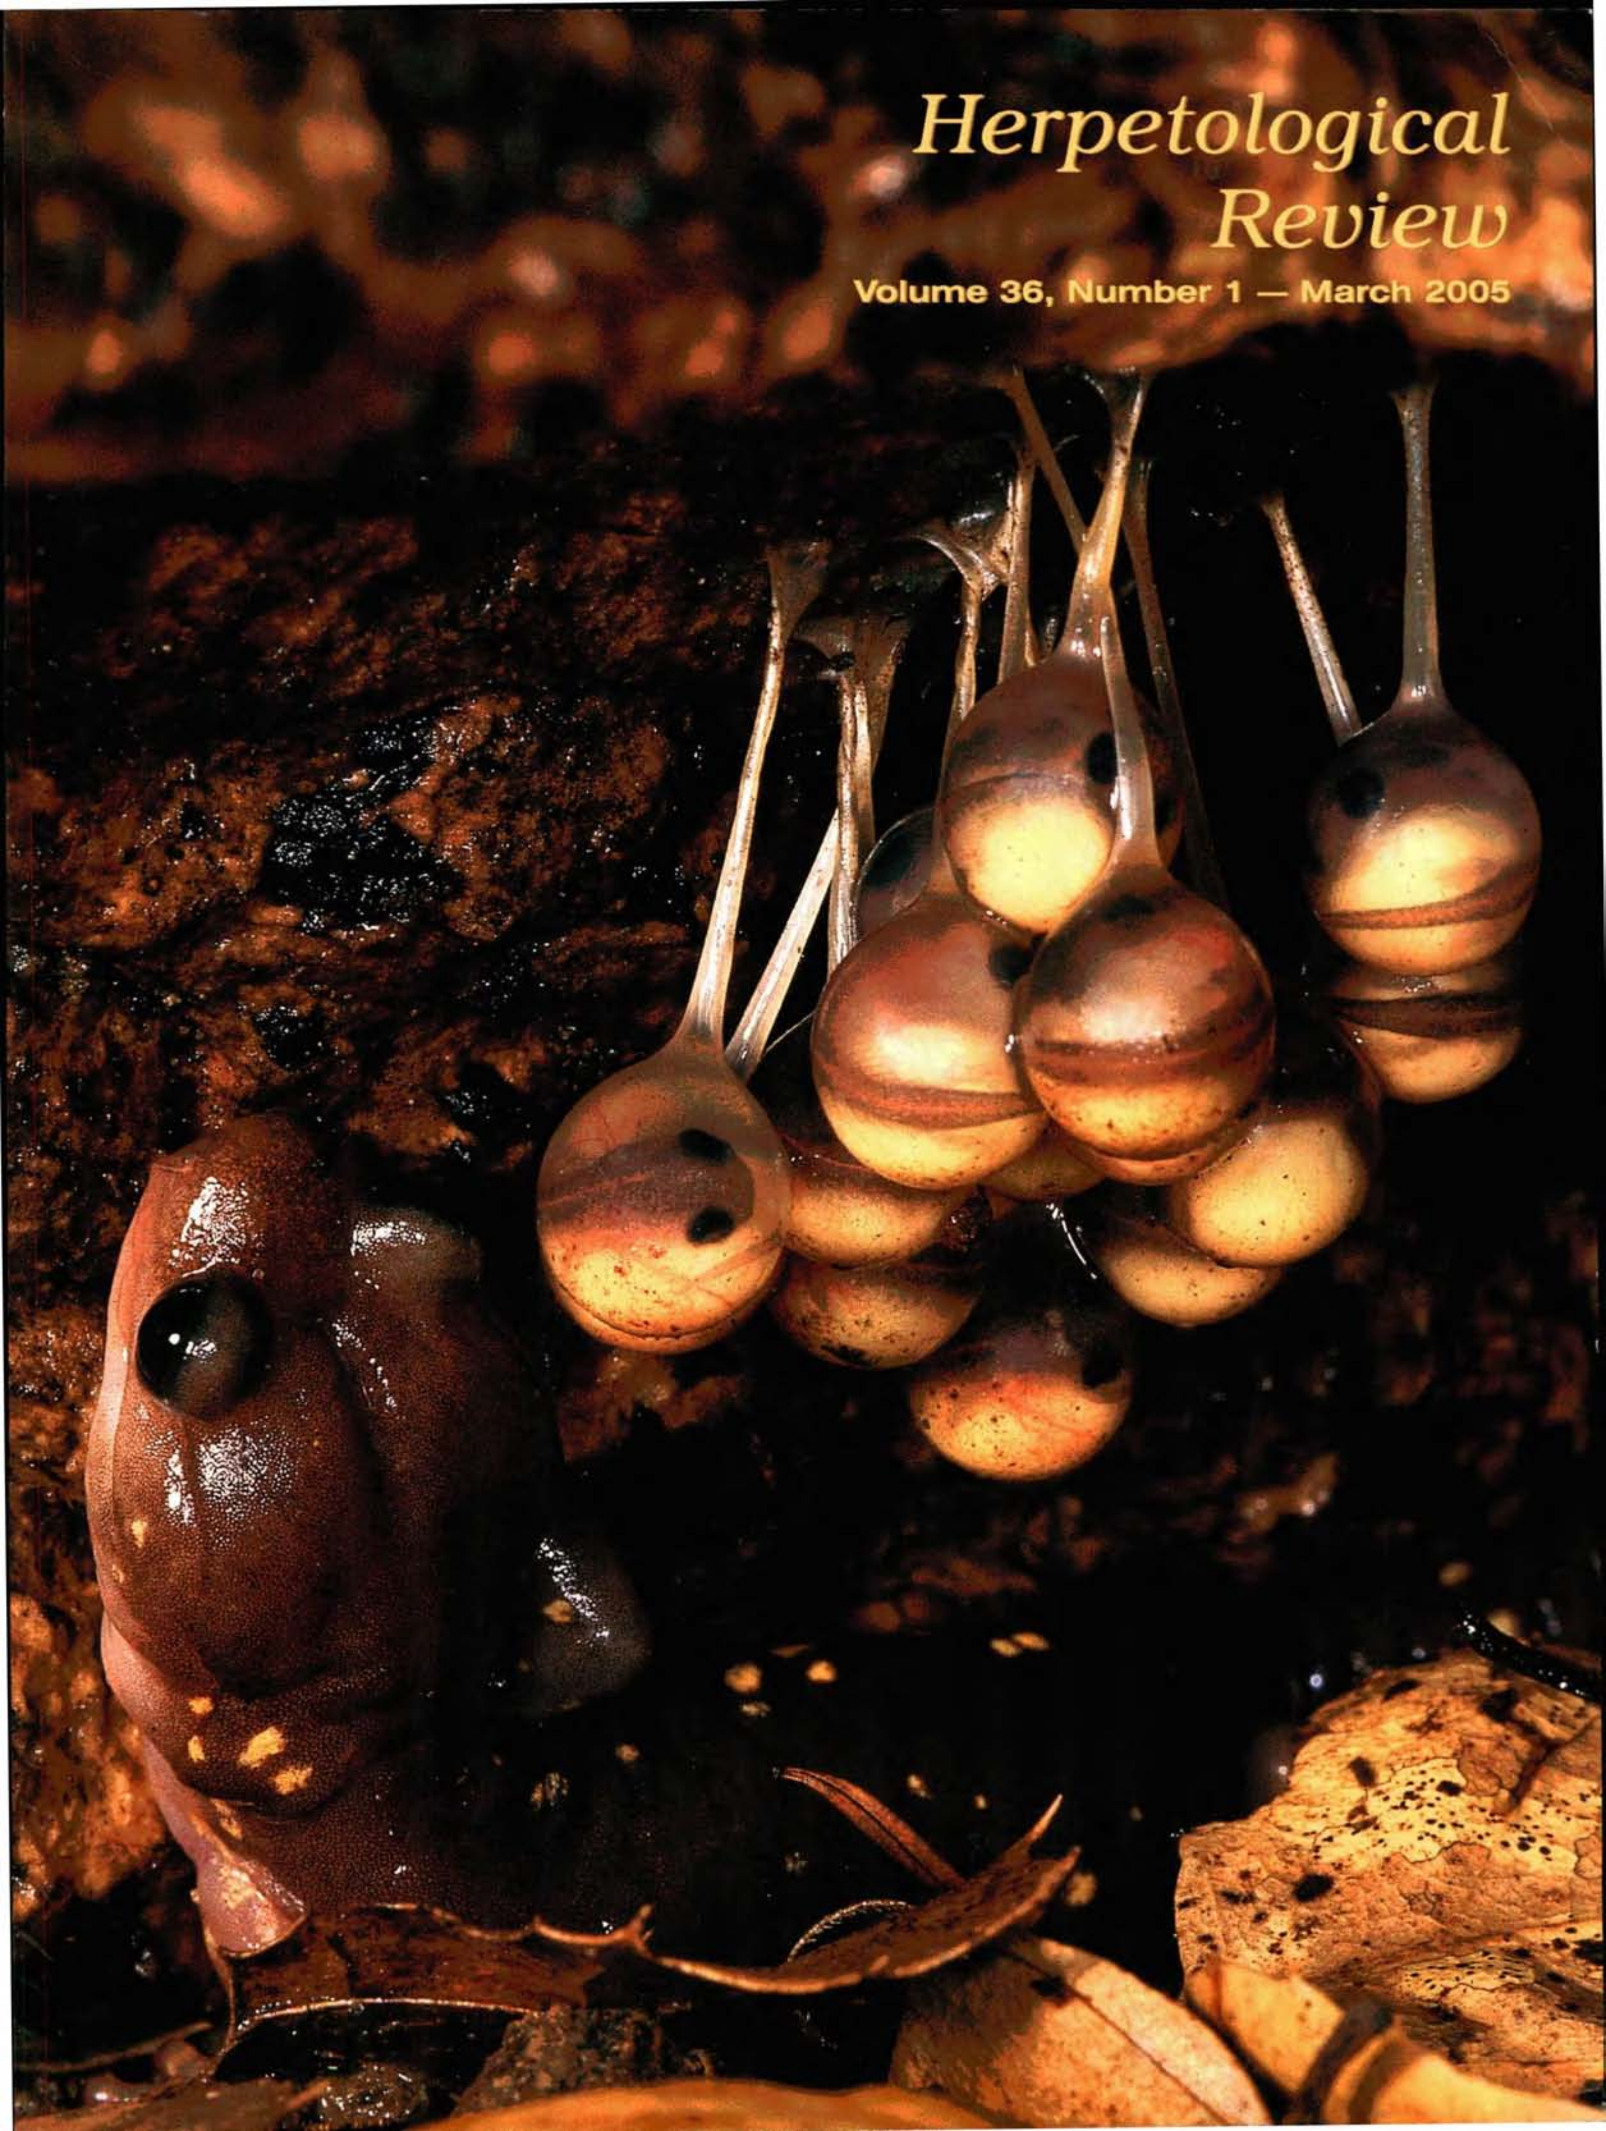
Some further comments. This geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens which have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality color slide or photograph may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Color slides and photographs *must* be deposited in a university or museum collection along with complete locality data, and the color slide catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary) to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extensions unless a thorough literature review has been completed.

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **Alan M. Richmond** (USA & Canadian records only); **Jerry D. Johnson** (Mexico and Central America, including the Caribbean islands); **Hidetoshi Ota** (all Old World records); or **Gustavo J. Scrocchi** (South American records). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Schmitz, A., and T. Ziegler. 2003. Geographic distribution. *Sphenomorphus rufocaudatus*. Herpetol. Rev. 34:385.

CAUDATA

NOTOPHTHALMUS VIRIDESCENS LOUISIANENSIS (Central Newt). USA: INDIANA: Posey Co: Point Township: 14 km SSW Mount Vernon at Twin Swamps Nature Preserve. 16 June 2004. Zack Walker, Nathan Engbrecht, Andrew Berger, and Michael Lodato. University of Michigan Museum of Zoology (UMMZ 232002–06). Verified by Greg Schneider. New county record and first record for "pocket" of extreme SW Indiana. (Minton 2001. Amphibians and Reptiles of Indiana. 2nd ed., revised. Indiana Acad. Sci. 404 pp). Newts appear to be common at this locality with its bald cypress (*Taxodium distichum*) and overcup oak (*Quercus* lyrata) swamps surrounded by mature forest. Adults



Herpetological Review

Herpetological Review

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

Society for the Study of Amphibians and Reptiles

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

Annual Dues and Subscriptions: Annual membership dues for the year 2005 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with Visa or MasterCard (account number and expiration date must be provided). Payment should be sent to: Theodora Pinou, SSAR Treasurer, Department of Biological & Environmental Sciences, Western Connecticut State University, 181 White Street, Danbury, Connecticut 06810, USA. Fax: (203) 837-8769; e-mail: PinouT@wcsu.edu.

Future Annual Meetings

2005 — University of South Florida, Tampa, Florida, 6–11 July (with ASIH, HL)
2006 — New Orleans, Louisiana, 12–17 July (with ASIH, HL)

About Our Cover: *Aneides lugubris*

The plethodontid salamander genus *Aneides* contains six species: four of these are confined to the Pacific Coast of North America, one occupies a small range in the mountains of south-central New Mexico, and a sixth ranges across the Appalachian Mountains of the eastern U.S. *Aneides lugubris*, the Arboreal Salamander, is the largest species in the genus (to 18 cm TL), and ranges from northern California to northern Baja California. It occupies habitats notably drier than for other members of the genus, extending its range southward to semi-arid chaparral habitat in northwestern Baja California. Over much of its range, *A. lugubris* is associated with large oak trees; salamanders occupy hollowed out sections of standing and fallen oaks, as well as rock crevices. A suite of morphological features—long limbs, expanded toe tips, and a prehensile tail—facilitate climbing (they have been found up to 18 m above ground in oaks). Dagger-like teeth, along with modifications of the jaws and skull, enable Arboreal Salamanders to capture and restrain relatively large prey.

Eggs, numbering 5–24, are laid in humid cavities in trees or beneath rocks or logs. The eggs are suspended on gelatinous stalks, an arrangement common to all members of the genus. The nest is attended by the female, and communal nesting is probably common. Recent reviews of the biology of *Aneides lugubris* are provided by Petranka (1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, D.C., pp. 322–325) and Staub & Wake (2005. *In* M. Lannoo, ed., Amphibian Declines: The Conservation Status of United States Species. University of California Press, Berkeley and Los Angeles).

The female salamander on our cover was found in a wooded area north of San Francisco Bay, California, and temporarily collected for photography by **Tim Paine**. During the first week of April, the female deposited 15 eggs beneath a slab of cork bark. She attended the nest throughout development, with hatching occurring in early June.

PHOTO BY DOUG MASON

The cover image was captured on Fuji Velvia film using a Nikon F4s camera equipped with a 105mm Micronikkor lens. Light was provded by SB-29s ringlight and SB-28 flashes. The exposure was 1/60 second at f22. Paine, whose avocation is herpetology, is a ten-year veteran of the San Francisco Police Department. With a B.S. in Biology, he has aspirations of returning to school for a Ph.D., but appreciates the freedom his current job affords for travel and photography.

SSAR BUSINESS

Announcing the 2005 Joint Meeting of Ichthyologists and Herpetologists 6–11 July 2005

The annual meeting of the Society for the Study of Amphibians and Reptiles, The Herpetologists' League, and the American Society of Ichthyologists and Herpetologists will be held 6–11 July 2005, hosted by the University of South Florida at the Marriott Tampa Waterside Hotel and Marina, Tampa, Florida. Please refer to the Joint Meeting website <http://www.dce.ksu.edu/jointmeeting/> for information on how to register for the meeting. All material typically included in the Call for Papers is now accessible on the website.

SSAR Election Results

Results of the 2004 SSAR election are as follows:

President-Elect: .... Roy McDiarmid

Secretary: .... Marion Preest

Treasurer: .... Theodora Pinou

Board Members (Class of 2008):

.... Rafe Brown, Meredith Mahoney

.... Jim McGuire, Richard Shine

Thanks to all of the nominees who agreed to stand for positions and to Maureen Kearney (Elector).

NEWSNOTES

Kansas Herpetological Society Annual Meeting

The Kansas Herpetological Society held its 31st Annual Meeting at Kansas State University in Manhattan, Kansas, on November 6–7, 2004. Approximately 110 participants attended scientific paper sessions presented by scientists and students from across the nation. Featured speaker was Alicia Mathis, professor at Southwest Missouri State University in Springfield. Dr. Mathis spoke about salamander conservation.

Daphne Jones, a student at Emporia State University, received the 2004 Howard K. Gloyd/Edward H. Taylor Scholarship, honoring the memory of two great biologists with strong ties to Kansas. The 2004 Alan H. Kamb Grant for Research on Kansas Snakes were made to Erik Bartholomew, a student at Fort Hays State University. Dwight R. Platt, Bethel College, was recognized as the seventh recipient of "The Suzanne L. & Joseph T. Collins Award for Excellence in Kansas Herpetology."

In 2005, the Society will meet at Pittsburg State University in Pittsburg, Kansas.

Amphibian Conservation and Zoos

Kevin Zippel of the Detroit Zoo has produced an excellent overview of zoo amphibian conservation programs; this document is now available online at Berkeley's AmphibiaWeb site:

<http://www.amphibiaweb.org/aw/declines/zoo/index.html>

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

19–22 June 2005—Hellbender Symposium, a conference on the biology of giant salamanders. Gaston's White River Resort, Lakeview, Arkansas (USA). Information: http://www.ozarkhellbender.com/.

19–24 June 2005—Fifth World Congress of Herpetology, Stellenbosch University Campus, Stellenbosch, South Africa. Information: http://www.wits.ac.za/haa/5wch.htm.

6–11 July 2005—48th Annual Meeting, Society for the Study of Amphibians and Reptiles, together with The Herpetologists' League and the American Society of Ichthyologists and Herpetologists. University of South Florida, Tampa (USA). Information: http://www.dce.ksu.edu/jointmeeting/.

27–30 July 2005—29th Annual International Herpetological Symposium, Scottsdale, Arizona (USA). Information: www.kingsnake.com/ihs.

15–19 August 2005—VII Latin American Congress of Herpetology, Universidad Autónoma del Estado de Morelos, Cuernavaca, Morelos, México. Information: http://www.ibiologia.unam.mx/barra/congresos/frame.htm.

OBITUARIES

Herpetological Review, 2005, 36(1), 2.

Madge Rutherford Minton 1920–2004

Madge Rutherford Minton, 84, well known to the herpetological world as the wife of and collaborator with Sherman Minton, died November 7th, 2004. While earning her B.A. degree at Butler University, she was one of the first four women in the United States to graduate from the Advanced Civilian Pilot Training Program authorized by the Civil Aeronautics Authority. In 1943 she joined the newly organized Women's Airforce Service Pilots (WASPs) and was trained to ferry Army airplanes to domestic military bases for delivery to combat flight crews. After World War II Madge remained passionate about the role of women in aviation. She was a member of The Ninety-Nines, Inc. International Organization of Women Pilots, P-51 Mustang Pilots Association, The Confederate Air Force, and the Indianapolis Aero Club. She served as a regional vice president for the P-47 Thunderbolt Pilots Association. In the 1970s Madge took an active role in lobbying for and finally achieving recognition and veteran status for all former WASPs.

While serving in World War II, Madge and Naval Officer, Sherman A. Minton, M.D. were married on October 10, 1944 during a five-day leave. After the war, they settled in Indianapolis. With the exception of four years in Pakistan (1958–1962), Indianapolis was the family's home. Madge, mother of three daughters, was a teacher, an author, a lapidary, and an amateur herpetologist. She was an accomplished collector of unique primitive artifacts, fine art, and natural rarities. The Mintons co-authored two popular books: "Giant Reptiles" and "Venomous Reptiles." The two of them were regular attendees at annual herpetological society meetings. After Sherman's death in 1999, Madge and her daughter Holly attended the 2001 HL/SSAR meeting in Indianapolis and inscribed many copies of Sherman's just-published memoirs (issued posthumously), "Life, Love, and Reptiles" (2001. Krieger Publishing Co., Malabar, Florida). Additional information on the life of Sherman and Madge Minton is provided in Bernard Bechtel's tribute to Sherman (1999. Herpetol. Rev. 30:202–204), as well as in Bechtel's chapter in "Life, Love, and Reptiles" (see pp. 183–198). The June 1999 issue of *Life* magazine contains a feature article about Madge in her role as a war-time pilot.

Contributions may be made to WASP Memorials, P.O. Box 456, Sweetwater, Texas 79556, USA. Madge is survived by her three daughters, Brooks M. de Cervantes, April M. Kiesier, and Holly S. Minton; and her grandchildren, Natasha Cervantes M.D., and Benjamin Childers.

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **María del Rosario Castañeda** or **Michele Johnson**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Nest Site Selection in Leatherback Turtles

A female sea turtle's nest placement can strongly influence the survival of her offspring, which must orient themselves seaward after hatching. In this study, the authors investigated whether nest site choice in leatherback turtles (*Dermochelys coriacea*) is random, or if individuals consistently choose nesting sites with certain characteristics. To test this, a number of ecological measures were taken for 41 multiply-nesting turtles in French Guiana. Individual females showed repeatable preferences for only one measure: nesting at certain distances from the highest spring tide line (HSTL). While nest placement in regard to HSTL is nonrandom, individuals did not demonstrate nest site fidelity for subsequent clutches. To determine the adaptive value of nest placement, the authors performed orientation experiments in five different environments using 100 newly-emerged hatchlings from each of five clutches in Suriname. Results from this experiment showed that hatchlings are able to orient seawards regardless of distance from the beach, except when they are released in vegetated areas. Together, these results indicate that nest placement may be inherited and that vegetation acts as a strong selective pressure on nesting patterns. The authors also discuss conservation implications of their findings.

Kamel, S. J., and N. Mrosovsky. 2004. Nest site selection in leatherbacks, *Dermochelys coriacea*: individual patterns and their consequences. Animal Behaviour 68:357–366.

Increase in Genetic Variation of Brown Anole Populations During Invasion

Although there are both ecological and genetic reasons why small populations may face the risk of extinction, some introduced species that initially experience these conditions seem to evolve rapidly and become invasive. The authors examined one aspect of invasion biology—the genetic variation of an invasive species—using the brown anole, *Anolis sagrei*. Genetic variation is expected to decrease during an invasion as the result of a population bottleneck, which would in turn limit the population's ability to adapt to novel environments. Using mitochondrial haplotypes from 600 individuals in native and introduced populations, the authors found instead that introduced populations of the brown anole in Florida have more genetic variation than populations from the lizard's native range. This is the result of repeated (at least eight) introductions from across the native range, which allowed the genetic mixture of populations from different geographic sources. Further, they found that more recent brown anole introductions around the world have come from Florida, and some of the introduced populations have maintained high levels of variation. These results suggest that multiple introductions may be one key to successful invasions, and that the more genetically variable introduced populations may be particularly effective at invading elsewhere.

Kolbe, J. J., R. E. Glor, L. Rodríguez Schettino, A. Chamizo Lara, A. Larson, and J. B. Losos. 2004. Genetic variation increases during biological invasion by a Cuban lizard. Nature 431:177–181.

Seed Dispersal by the Florida Box Turtle

Seed dispersal by animals is a well-studied plant-animal mutualism; however, dispersal of seeds by reptiles has been the focus of few investigations. The authors examined the effects of digestion by the Florida Box Turtle (*Terrapene carolina bauri*) on seed dispersal and germination in pine rockland forests. In fecal samples from 145 turtles, they found seeds of 13 plant species, equivalent to 39% of locally-occurring species with fleshy fruits. The authors then planted recovered seeds from nine of these species, and seeds of each species germinated. Germination experiments using two palm species (*Thrinax morrissii* and *Serenoa repens*) and a shrub (*Byrsonima lucida*) were performed with three treatments: seeds from box turtle feces, control seeds (i.e., collected from plants) with intact fruit, and control seeds with the fleshy fruit removed. Results from these experiments indicate that larger seeds are more likely to germinate after turtle digestion, while smaller seeds may become dormant as a result of digestion. In addition, removal of fruit from ungerminated seeds (manually or through digestion) may allow seeds to escape from insect predation. Together, these findings suggest that box turtles, with home ranges as large as 5 ha, may play an important role in seed dispersal.

Liu, H., S. G. Platt, and C. K. Borg. 2004. Seed dispersal by the Florida box turtle (*Terrapene carolina bauri*) in pine rockland forests of the lower Florida Keys, United States. Oecologia 138:539–546.

Morphological Homoplasy in Plethodontid Salamanders

Plethodontid salamanders comprise more than two-thirds of salamander species and exhibit extreme morphological homoplasy, yet no well supported molecular phylogeny exists for this group. To address this problem, the authors sequenced the complete mitochondrial genome for 24 taxa, representing 17 plethodontid genera and two outgroups. These partitioned and unpartitioned sequence data were analyzed using Bayesian statistics, maximum likelihood, and maximum parsimony. The analyses generated congruent trees that surprisingly, reject the monophyly of three of four major plethodontid groups whose relationships have previously been based on morphological characters. The revised phylogeny suggests that a larval stage re-evolved multiple times from a direct-developing ancestor, and that the scenarios for convergent evolution of projectile tongues, toe number, and tail auto-

tomy should be reconsidered. These results indicate that certain morphological traits may be more evolutionarily labile than previously thought. Furthermore, the proposed phylogeny provides no support for the "Out of Appalachia" biogeographic hypothesis for plethodontids. The authors advocate the use of multiple genetic markers for taxonomic revision of this group and to provide a better understanding of morphological evolution.

MUELLER, R. L., J. R. MACEY, M. JAEKEL, D. B. WAKE, AND J. L. BOORE. 2004. Morphological homoplasy, life history evolution, and historical biogeography of plethodontid salamanders inferred from complete mitochondrial genomes. Proceedings of the National Academy of Sciences 101:13820–13825.

Yolk Partitioning in Lizard Embryos

Reptilian females deposit yolk in their eggs that provides nutrition for the embryos within. After embryonic growth in many species, a portion of this yolk remains and is drawn into the hatchling's body before hatching. This residual yolk may be a maternal contribution to maximize hatchling size, or it may be the result of active partitioning by the embryo between early growth and reserve post-hatching energy. To test these, the authors manipulated eggs from five females of the lizard *Calotes versicolor*. They found that eggs for which 8% of the yolk was experimentally removed (N = 44) produced smaller hatchlings than sham operated eggs (N = 43), and that manipulated eggs hatched after a shorter incubation period. However, the same amount of residual yolk remained for eggs in both groups. This indicates that embryos of this species can partition available yolk, and that post-hatching energy needs balance the advantage of larger hatchling body size.

RADDER, R. S., B. A. SHANBHAG, AND S. K. SAIDAPUR. 2004. Yolk partitioning in embryos of the lizard, *Calotes versicolor*: maximize body size or save energy for later use? Journal of Experimental Zoology 301A:783–785.

Frog Community Persists Despite Endemic Chytrid Infection

Although the chytrid fungus (*Batrachochytrium dendrobatidis*) has been implicated as a causal agent in worldwide amphibian decline, little information is available regarding the impact of the fungus in natural populations. The authors performed a retrospective histological analysis of toe tips from six sympatric frog species in Queensland, Australia, collected ten years after a period of rapid decline. They determined that while four of the species were free of infection, two species, *Taudactylus eungellensis* (which experienced a population decline) and *Litoria wilcoxii/jungguy* (whose population remained stable), had been infected. Additionally, the authors conducted a mark-recapture study of infected and uninfected individuals in remnant populations of these two species and found no evidence of differential survival as a result of infection status. These results refute the hypothesis that frog populations recovered after the fungus had disappeared, and suggest that perhaps an evolved resistance to the pathogen allows frog populations to persist with stable, endemic infections of the chytrid fungus.

RETALLICK, R. W. R., H. MCCALLUM, AND R. SPEARE. 2004. Endemic infection of the amphibian chytrid fungus in a frog community post-decline. Public Library of Science Biology 2:1965–1971.

Molecular Phylogeny of Caecilians

Caecilians are a remarkably diverse, yet little known, order of amphibians with six currently recognized families. To resolve the relationships among these families, the authors used complete sequences of the mitochondrial genome and the nuclear RAG1 gene from one representative of each family. Sequences were combined with data from other amphibians and subjected to separate and combined phylogenetic analyses using maximum parsimony, minimum evolution, maximum likelihood, and Bayesian inference. Results strongly supported the monophyly of the three orders of Amphibia and are consistent with a monophyletic Batrachia hypothesis. Within Gymnophiona, the optimal tree corresponds with recent morphological and molecular studies; however, relationships among higher caecilians remain unresolved.

SAN MAURO, D., D. J. GOWER, O. V. OOMMEN, M. WILKINSON, AND R. ZARDOYA. 2004. Phylogeny of caecilian amphibians (Gymnophiona) based on complete mitochondrial genomes and nuclear RAG1. Molecular Phylogenetics and Evolution 33:413–427.

Adaptations of Cold-Climate Reptiles

Cold-climate reptiles have three adaptations that provide a warmer environment for incubating embryos despite low ambient temperatures: maternal nest placement in warm sites, viviparity (embryos retained in the uterus are presumably more protected from low temperatures than those in nests), and increased basking during pregnancy. To determine the thermal consequences of these traits in sympatric Australian reptiles, the author measured temperatures of potential and actual nest sites of the oviparous skink *Bassiana duperreyi* and body temperatures of pregnant and non-pregnant viviparous skinks *Eulamprus heatwolei*. He found that nest site selection had a larger effect on average incubation temperatures than viviparity or maternal basking in cold climates. In particular, he showed that viviparous skinks provided embryos with bimodal daily thermal distributions rather than the unimodal distributions of nest temperatures; however, mean temperatures

between nests and females did not differ. Additionally, although pregnancy alters thermoregulatory behaviors, in cold climates effective basking opportunities may be severely limited. These conclusions contradict the paradigm under which pregnant heliothermic squamates are expected to maintain higher body temperatures than nest temperatures, and suggest that basking should be considered a preadaptation rather than an adaptation for viviparity.

SHINE, R. 2004. Incubation regimes of cold-climate reptiles: the thermal consequences of nest-site choice, viviparity and maternal basking. Biological Journal of the Linnean Society 83:145–155.

Molecular Phylogeny of Squamates

Squamate reptiles are model systems for many ecological and evolutionary studies, and an accurate phylogeny is critical in drawing generalizations from such studies. In particular, the traditional morphology-based dichotomy between Iguania and Scleroglossa has been correlated with major evolutionary changes within Squamata, inferences that rely on correct rooting of the squamate tree. The authors present a molecular phylogeny of 69 squamate species representing all major clades and most major subclades, using 4600 bp of DNA sequence from three independent data sets: the nuclear genes *RAG-1* and *c-mos* and the mitochondrial *ND2* region. These sequences were subjected to separate and combined analyses using maximum likelihood, Bayesian statistics, and maximum parsimony. Results supported the monophyly of almost all recognized families, but found that several higher taxa do not form monophyletic groups. Iguania, previously considered the sister group of Scleroglossa, comes out deeply nested within Scleroglossa. Also, limbless taxa including snakes, amphisbaenians, and dibamid lizards appear to have independently evolved the limbless condition. Several other taxonomic groupings, suggested or confirmed by the new data, are also discussed.

TOWNSEND, T. M., A. LARSON, E. LOUIS, AND J. R. MACEY. 2004. Molecular phylogenetics of Squamata: The position of snakes, amphisbaenians, and dibamids, and the root of the squamate tree. Systematic Biology 53:735–757.

Sexual Dimorphism in the Cottonmouth Snake

While sexual selection is often cited as the cause of sexual dimorphism, natural selection that reduces intersexual resource competition is an important alternative explanation. The authors measured sexual dimorphism in head shape, a trait functionally related to resource use, in the cottonmouth snake *Agkistrodon piscivorus* using museum specimens (108 males, 106 females). They also determined intersexual differences in prey type and prey shape by dissecting the stomachs of those specimens. A principal component analysis revealed that overall head size and several aspects of head shape differ in males and females. Analysis of stomach contents showed that the sexes consume qualitatively different prey and that males consume significantly taller prey than females. Cottonmouth snakes are gape-limited predators, and the head shape differences observed in this study may reflect functional differences in maximum gape, which would in turn explain differences in consumed prey height between similarly sized males and females. However, as differences in prey may be the result of sexually-selected body size dimorphism, the authors encourage comparative studies on sexual differences in snakes to determine the generality of their findings.

VINCENT, S. E., A. HERREL, AND D. J. IRSCHICK. 2004. Sexual dimorphism in head shape and diet in the cottonmouth snake (*Agkistrodon piscivorus*). Journal of Zoology 264:53–59.

Consumption of Toxic Prey as Protection From Predation

Although many amphibians secrete toxic compounds that are lethal to most predators, a number of snake predators have evolved resistance to these toxins. Common Garter Snakes (*Thamnophis sirtalis*) and their prey, the Rough-skinned Newt (*Taricha granulosa*) are an example of such a system. The authors investigate patterns of accumulation of tetrodotoxin (TTX), a neurotoxin produced by the Rough-skinned Newt, in garter snakes after ingesting newts, and consequences of that accumulation. After assuring that snakes were free of TTX, 15 snakes were each fed one newt of known toxicity; snake liver tissues were subsequently collected at weekly intervals to assess TTX retention. Data from this study show that after consuming a single newt, snakes retain TTX in the liver for a minimum of one month at levels that would incapacitate, if not kill, avian predators of the snake and would negatively affect mammals as well. After eating 3–8 newts, snakes harbored the toxin in their livers for at least seven weeks. The authors conclude that the concentration of TTX in the liver, away from the sites of action for the toxin, may serve as chemical protection against predation for garter snakes, as predators may quickly learn to avoid prey that are likely poisonous.

WILLIAMS, B. L., E. D. BRODIE, JR., AND E. D. BRODIE III. 2004. A resistant predator and its toxic prey: persistence of newt toxin leads to poisonous (not venomous) snakes. Journal of Chemical Ecology 30:1901–1919.

ZOO VIEW

The Sad Tale of Two Zoos

The Belle Vue Zoological Gardens in Manchester, England, established in 1836, was important in the history of zoo herpetology (Fig. 1). The Zoo was not a conventional zoological garden but was part of an amusement park. There are fascinating historical documents concerning this Zoo: average longevity for 24 chameleons between the years 1898–1901 was slightly over three months and none survived for one year (Flower 1925), description of the reproduction of a pair of Seba Pythons (*Python sebae*) and exhibition of fertilized eggs by the Secretary of the London Zoological Society (Jennison 1909), a letter by George Jennison to the Secretary of the London Zoological Society describing reproduction and behavior of a pair of Pine Snakes (Jennison 1910), and studies on the mating behavior of American Alligators (Legge 1969).

Like many inner-city institutions, it faced shrinking financial support and visitation in the 1970s. Increasing vandalism was a major problem: windows in the glass roof were replaced five times within two months. The number of species over one twenty-year span was extraordinary: 6 salamanders, 15 anurans, a caecilian, 8 crocodilians, 41 chelonians, 94 lizards, and 106 snakes. These included the Chinese Giant Salamander, Marine and Rhinoceros Iguanas, False Gavial, African Dwarf and Slender-snouted Crocodiles, Galápagos and Aldabran Giant Tortoises and many unusual snakes. The herp staff created naturalistic exhibits with living plants — American Alligators bred in their enclosure for the first time in a European zoo. The complete story is told in a book by Clive Bennett and David Barnaby, published in 1989: "The Reptiles of Belle Vue 1950–1977. A Curator's Viewpoint." The Zoo closed in 1977.

Fig. 1. Front cover of visitor guide to Belle Vue Gardens in 1895. Courtesy of Smithsonian Institution Libraries, Washington, DC.

In 2004, the same fate as that of Belle Vue befell the Baltimore Zoo's herpetology department. Because of declining financial support for the Zoo, administrators decided that the reptile building, located outside the zoo boundaries in Druid Hill, needed to be closed. The collection was disbanded and the staff was declared to be redundant.

This facility opened on 12 August 1948 and Frank Buck of "Bring-Em-Back-Alive" fame was the guest of honor. Six months later, the late Frank Groves, Head Keeper of Birds, was placed in charge after his predecessor John E. Cooper (now at North Carolina Museum of Natural Sciences) opened the building before leaving the Zoo. Groves was elevated to Curator in 1973 and remained at the Zoo in this capacity until he retired sixteen years later (Fig. 2). He published many papers, some of which are listed below.

According to "International Zoo Yearbook" (1998:Volume 28), composition of the collection was nearly 90 taxa of reptiles with 365 specimens and 24 taxa of amphibians numbering 234. Virtually all of these specimens from this important collection will be sent to other facilities.

The charge associated with this article was the more-or-less straightforward question: how can zoo-academic collaborations work effectively? Although the authors have participated in a fair number of such collaborations that resulted in publications as well as oral presentations at scholarly meetings, we have never thought of our efforts as having been special in any way, nor have we imagined that any unusual providence (other than the asking of interesting herpetological questions) directed our work. Accordingly, we are not sure why our collaborations have worked and why some others have not. One idea we must consider is that there are dozens of potentially successful collaborators out there who have not yet hooked up with zoos because of various inertial forces. That is, the real problem is not only a matter of specific protocols and experimental designs, it is also a matter of too few bodies in the population of academic-zoo collaborators. This problem has been recognized by persons on both sides of the dyad, and is being dealt with through appropriate published invitations and conferences; hence, no more will be said about this matter in the present article. Another hypothesis that came quickly to mind is that we have been keenly interested in the questions that our data-gathering efforts were designed to answer, and this interest usually generated plenty of energy in us and maybe it generated a bit of sympathetic energy in our zoo colleagues. Motivation is certainly an important commodity, as this is the stuff that helped us get from Boulder to San Diego and to Dallas and to Washington, D.C. and to various other cities containing collaborating zoos. And, of course, once we arrived at the zoos, it was also necessary to make observations and to manage the empirical data that accumulated as a consequence. Lest we forget, energy was also necessary to write the proposals that were universally necessary to gain access to zoo collections, and plenty more energy was required to write the final papers.

So, could our successes be attributed to the energy-generating interest we had in the predatory behavior of rattlesnakes? Maybe, but we believe this is an arrogant position because it implies that other erstwhile zoo-oriented academics had less interest in their questions than we had in ours, and this cannot be. Virtually all herpetologists tend to be reasonably passionate about their interests, hypotheses and organisms, and we can't claim to have been unusual in this respect. Furthermore, while the authors are reasonably affable people, and while friendships with zoo-based collaborators certainly facilitate research, we do not think our collective affability is unusual. Indeed, each of us thinks the other is just barely above threshold in this department, a conclusion that would probably be seconded by our most frequent zoo collaborators (J. B. Murphy and C. W. Radcliffe).

Having rejected these ideas, we must look away from our personal attributes and toward the nature of the science we have done during our collaborations. This is not to say that the personal characteristics were irrelevant; they may have been necessary but they were not sufficient. For Aristotelian completeness in our analysis, we must go on to consider the structure of the questions we asked, the data we gathered, and the conclusions we reached. What we will say in the following paragraphs is, in our view, equally applicable to other successful zoo-academic collaborations known to us (e.g., projects done by C. C. Carpenter, W. E. Cooper, Jr., C. Gans, J. Gillingham, H. W. Greene, to name a few).

Some scientific questions can be meaningfully answered by studying zoo animals, whereas other questions require either more controlled (laboratory) environments or completely natural ones. It has been our good fortune to deal with questions that lent themselves to zoo collections. In particular, we have pursued numerous studies of strike-induced chemosensory searching (SICS) and related behaviors, using zoo collections to demonstrate the generality of the phenomena, as the research collection in our laboratory contained only a few species of rattlesnakes and we had good reason to believe that SICS occurred generally among pit vipers as well as in old world vipers, elapids and even in some non-ven-

omous species. Our zoo collaborations revealed this to be true, as have the research efforts of others working independently. In retrospect, it would be almost impossible to explore the herpetological generality of any appropriate behavioral or physiological phenomenon without partnering with at least a few zoos.

Our work with zoos hinges on an important assumption, namely, that SICS and related behaviors seen in long-term captive specimens are representative of the same events in free-living individuals. Although observations of predation in wild snakes are relatively rare, those that have been published are generally supportive of our assumption, lending ecological validity to both our laboratory work and the zoo studies. This factor undoubtedly contributes to the willingness of zoos to support the work by granting access to their collections and even participating in the data-gathering efforts.

Another factor that almost certainly played a role in the success of our collaborations has to do with the design of the experiments and the protocols associated with their execution. Our SICS experiments conform to a fairly standardized set of operations that have three properties, all of which are relevant in the present context. First, the operations are fairly straightforward, easy to comprehend and equally easy to carry out. Second, minimal danger is involved, either to the observers or to the animals. And, these matters are easy to supervise by zoo staff. Third, although the actual recording of data can be a bit tedious, the authors have generally done this work, so that we have been little or no burden on the zoo staff. Of course, we have needed some help from the staff, but we have always kept this to a minimum unless some persons actually volunteered their time and effort. In this connection, it should be noted that we make our observations through the glass fronts of otherwise closed and locked cages, frequently from public viewing areas, so that valuable time of zoo staffers is not required for continuous supervision. Likewise, it should be noted that animals need not be taken off exhibit in order for DC and HMS to do their work.

Once the data have been gathered, we have adhered to three policies regarding the preparation of manuscripts. First, we tried to generate a draft as quickly as possible, usually within a month of completing the collection of data. Second, the draft was forwarded to the zoo staffers with whom we have worked for their comments and for final decisions regarding co-authorships. Third, our zoo collaborators frequently had a chain-of-command through which the final manuscript must circulate for approval(s), and we never tried to rush this process, nor have we ever submitted a manuscript for editorial review until the zoo collaborators have said this was okay. Sometimes revisions have been required at this stage and these have been cheerfully executed.

Some experiments, particularly those involving trail-following behavior, are inherently more complicated and more tedious to execute than are the SICS experiments. Nevertheless, we have always used the clearest possible protocols, minimizing the complexities as well as the necessary equipment, and streamlining as much as possible the data-gathering procedures. In several cases, zoo staffers have taken responsibility for collecting data, and we have always tried to remain available by phone for advice, as needed. As our collaborators have developed skill in the design and analyses of experiments, they have become independent researchers, conducting their own projects with little or no assistance from us. Possibly the best indicator of the success of a collaboration is to see the collaborators carry on themselves, establishing their own lines of inquiry and their own publications.

By way of conclusions, we can tender five assertions: (1) only certain problems lend themselves to research with zoo collections and vice versa; (2) there are, however, a reasonable number of behavioral, life history and physiological issues that fall into this bailiwick, so we need not worry that our issue-domain is too restrictive, even if we rule out all forms of invasive experimentation; (3) simple and straightforward procedures are generally to be preferred over more complicated ones, especially for projects to be carried out in the limited facilities of most zoos; (4) credit should always be given to co-operating institutions, either in the form of an acknowledgment or co-authorship, as appropriate; and (5) manuscripts should always be circulated among collaborators and their chains of command, if necessary, prior to submission to journals.

Unfortunately academia is no longer the lodestone that it was in times past, because the very areas of potential research available in zoos now get relatively little emphasis in universities; appropriate collaborators are declining in number as a consequence of the de-emphasis of natural history and related fields. Nevertheless, there still are enough relevant academics to justify the relationship-building efforts of zoo professionals. The following anecdotes represent two points of light, so to speak, that can attract collaborators and point the way toward fascinating projects. A curator observed a strange behavior of a snake that formed a loop of itself, tail in mouth, to foil another snake that attempted to swallow it, with the latter snake ultimately giving up after mouthing the loop several times. In our lab, a whipsnake was observed seeking a lizard prey that could be detected only by its movement. The whipsnake thrashed its tail about while holding its head alert and steady, the tail apparently calculated to make the lizard reveal itself by movement while the snake's head was ready to strike. As long as there are zoo and academic professionals who appreciate such stories, there will be a basis for friendships and joint studies; there will also always be an element of serendipity attending such collaborations.

Herpetological Review, 2005, 36(1), 9–12.

Using Limb Morphology to Distinguish Two-lined Salamander Larvae (*Eurycea*) from Northern Dusky Salamander Larvae (*Desmognathus*)

ROBERT D. DAVIC
Ohio Environmental Protection Agency
2110 East Aurora Road, Twinsburg, Ohio, 44087-1969, USA
e-mail: robert.davic@epa.state.oh.us

The Northern and Southern Two-lined Salamanders (*Eurycea bislineata, E. cirrigera*) have syntopic distribution with the Northern Dusky Salamander (*Desmognathus fuscus*) over a wide geographic area of eastern United States and Canada (Petranka 1998). A third member of the Two-lined Salamander complex, *Eurycea wilderae*, (see nomenclature of Collins and Taggart 2002) overlaps with *D. fuscus* within the Blue Ridge Physiographic Region of the Southern Appalachian Mountains (Petranka 1998).

Accurate identification of the larvae of these species can be a difficult task for both professional and amateur herpetologist alike. My investigation of voucher specimens at The Ohio State University Museum of Zoology revealed some collections where small Two-lined Salamander larvae were incorrectly identified as *D. fuscus*. Rocco et al. (2004) report that volunteers trained to monitor streamside salamander populations have problems separating *E. bislineata* larvae from *D. fuscus*. Of 58 *E. bislineata* larval vouchers, 18 (31%) were incorrectly identified, and 16 of the 18 (89%) were keyed to *D. fuscus*. Others also have found that students have difficultly with accurate identification of the larvae of these two species (Daryl Karns, pers. comm.). More often than not, when misidentification does occur, it is an *E. bislineata* larva that will incorrectly be identified as *D. fuscus* (Rocco et al. 2004).

A number of taxonomic keys have been proposed to help distinguish the larvae of the nominate Two-lined Salamander species (*E. bislineata*) from *D. fuscus* using characteristics of gill morphology (Brandon 1964; Downs 1989; Petranka 1998). However, manipulative gill based taxonomy for salamander larvae is not appropriate for live specimens, can deform gills of museum voucher specimens, and is not practical for amateur herpetologists that lack access to a microscope. Less destructive visual morphological characters have been proposed. Live *D. fuscus* larvae tend to have white or silvery gill pigment, whereas the gills of Two-lined Salamander larvae are darkly pigmented and tend to be longer and more feathery (Valentine 1989; see also gill color in Plate 17-*D. fuscus* and Plate 20-*E. bislineata* of Petranka 1998). Brandon (1964) used the number and size of pale dorsal spots as a

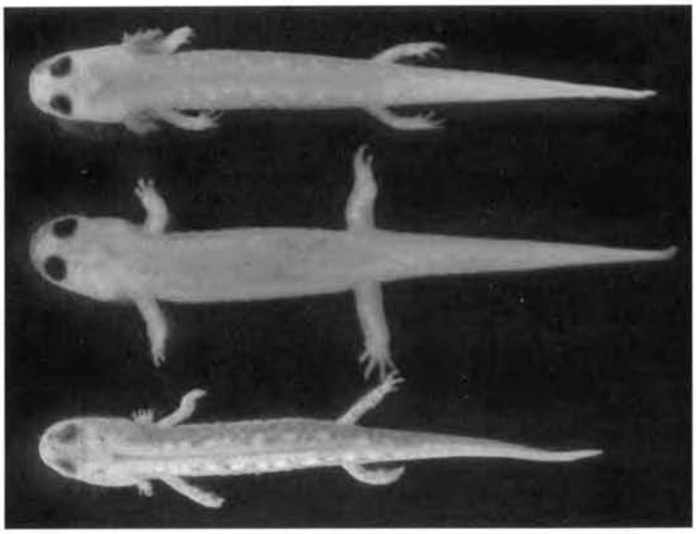

FIG. 1. Photograph of larval *Eurycea bislineata* (top, Geauga County, Ohio), *Desmognathus fuscus* (middle, Summit County, Ohio), and *Eurycea cirrigera* (bottom, Athens County, Ohio). The *D. fuscus* specimen is approximately 25 mm total length. Note the obvious difference in limb morphology of *D. fuscus* as compared to both *Eurycea* species.

taxonomic character, usually fewer in number and larger in *D. fuscus* larvae compared to *E. bislineata* (see also dorsal pattern for *D. fuscus* larvae in Bishop and Chrisp 1933).

While the above mentioned visual characters are helpful, there are problems with their use for taxonomy. The silvery color of *D. fuscus* gills may become discolored on preserved voucher specimens. Some recently hatched Two-lined Salamander larva may have gill length similar to dusky larvae (see *E. cirrigera* in Fig. 1). Ontogenetic and geographic variation in dorsal spot patterns also can lead to misidentification. According to Brandon (1964), older *D. fuscus* larvae (ca. 25–30 mm TL) may lose nearly all traces of light dorsal spots and replace these dots with a wavy dorsal pattern, thus reducing the usefulness of this character for taxonomy. To add to the confusion, dorsal spots of older Two-lined Salamander larvae also can merge to form a wavy dorsal pattern, making them appear very similar to large *D. fuscus* larvae to the untrained eye (pers. obs.).

Here, I present two new salamander taxonomic characters, the *limb length/width ratio* (Limb L/W), and the *hind limb width/SVL ratio* (HLW/SVL), which can be used to distinguish larvae of the Two-lined Salamander complex (*E. bislineata, E. cirrigera,* and *E. wilderae*) from *D. fuscus* larvae. I caution that these measures should be used only after regional taxonomic keys for salamander larvae eliminate other genera (e.g. Altig and Ireland 1984; Petranka 1998).

Salamander larvae of *E. bislineata* (N = 10), *E. cirrigera* (N = 8), and *D. fuscus* (N = 10) were collected from 16 populations located in 10 Ohio counties at various dates between 1999 and 2003. Geographic distributions for *E. bislineata* and *E. cirrigera* were determined using the range maps provided by Pfingsten (1998). For each species, individuals were selected for statistical analysis from a variety of populations to represent regional variation. Recent hatchings of all three species were included in the analysis. According to Petranka (1998), *D. fuscus* has a larval period less than one year throughout its range, thus I included specimens from both Two-lined Salamander species such that they overlap the reported maximum body length of *D. fuscus* larvae (about 30 mm according to Brandon 1964). In Ohio, Two-lined Salamanders have a two year larval period (Pfingsten and Downs 1989), thus it is likely that both year classes are represented in my samples. Total body length (TL) and snout-posterior vent length (SVL) were measured to 0.1 mm using a dial caliper. All specimens were fixed in 10% formalin, rinsed in distilled water, and stored in 70% ETOH.

Visually distinct differences are present in the relative width and length of fore and hind limbs of *D. fuscus* compared to Two-lined Salamander larvae of similar length (Fig. 1). In order to quantify these differences, limb measurements were made using an ocular micrometer fitted to a binocular microscope. The same magnification was used for all limb measurements taken on any given specimen. With the specimen positioned ventrally using forceps, the length of the proximal segment of the fore limb (humerus associated) and hind limb (femur) was measured starting from a point where the joint angle of the humerus and femur articulate with distal limb segments, then extending to the body (Fig. 2). The length of the fore limb was measured near the anterior margin; hind limb length was measured near the posterior margin (Fig. 2). It is helpful if the limbs are extended away from the body. The joint angle between the proximal and distal elements is usually clearly demarked. However, because the knee of the hind limb tends to point in an anterior direction in amphibians (Noble 1954), the exact location where the femur articulates with its distal limb segment often must be approximated. These two length characters are identified as FL (proximal fore limb length) and HL (proximal hind limb length). Limb width was measured where the humerus and femur articulate with the body, at an angle perpendicular to the FL and HL measurements (Fig. 2). The two width char-

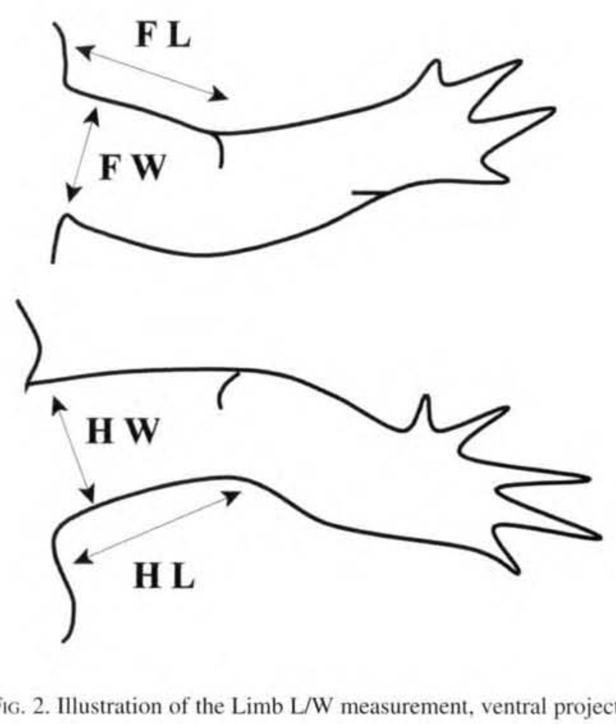

FIG. 2. Illustration of the Limb L/W measurement, ventral projection. FW = Forelimb Width; FL = Forelimb Length; HW = Hindlimb Width; HL = Hindlimb Length. Measurements are taken using an ocular micrometer fitted to a binocular microscope.

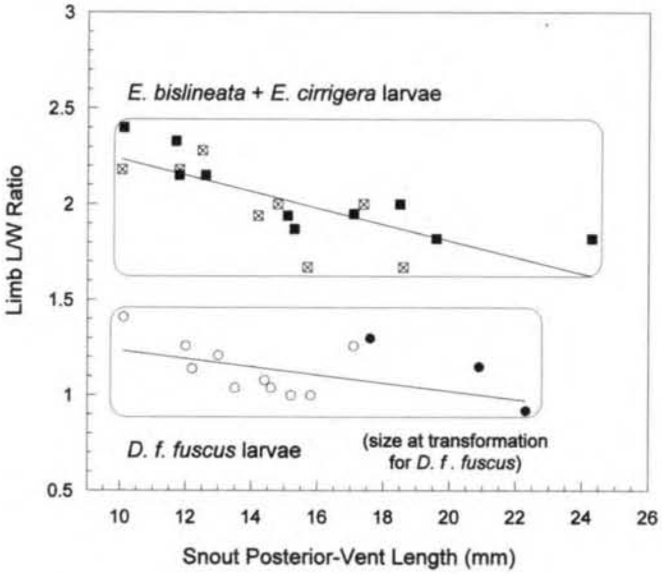

FIG. 3. Scatter plot of Limb L/W measures vs snout posterior–vent length for larvae of *Eurycea bislineata* and *Eurycea cirrigera* compared to *Desmognathus fuscus*. Solid squares = *E. bislineata* larvae; open squares = *E. cirrigera* larvae; open circles = *D. fuscus* larvae; solid circles = *D. fuscus* transformed juveniles. Lines represent least square regression; boxes outline the range of data points for each regression.

acters are identified as FW (proximal fore limb width) and HW (proximal hind limb width). Measures were taken on two limbs from the same side of the body.

Using the above measurements, a dimensionless limb length/width ratio was formulated as [(FL+HL) / (FW+HW)] = Limb L/W. For example, a larva of *E. bislineata* collected 18 Nov 1999 had a total body length of 20.0 mm and SVL of 11.8 mm. Measures on the fore limb were (FL = 13 micrometer units; FW = 6 units); measures on the hind limb were (HL = 15 units, HW = 7 units). A limb length/width ratio was calculated as [(13+15) / (6+7)] = 28/13 = 2.15]. Because the Limb L/W ratio is a dimensionless character, it may be calculated at any microscopic (or photographic) magnification, but the same magnification must be used for all measurements on any given specimen.

Limb L/W ratios were regressed for all three species against SVL to determine ontogenetic variation (Fig. 3). Because no visual difference was found in the regression data for *E. bislineata* and *E. cirrigera* (Fig. 3), they were combined for comparison with *D. fuscus*. The results indicate that the larvae of *D. fuscus* can be distinguished from the larvae of both *Eurycea* species at any body size using the Limb L/W measurement (Fig. 3). All larvae with a Limb L/W ratio less than 1.6 are identified as *D. fuscus* at any body size. In all three species, the Limb L/W ratio decreases with increasing body size (Fig. 3).

According to Brandon (1964), and Altig and Ireland (1984), accurately identified *D. fuscus* larvae have a total body length less than 30 mm. The largest *D. fuscus* larvae in Fig. 3 (collected 06 June 2003 from Geauga county) had SVL = 17.1 mm and TL = 31.3 mm, with gills that were nearly absorbed, an indication the larva was near transformation. Measurements on three small juvenile *D. fuscus* gave Limb L/W ratios that fit well the extrapolated regression curve for *D. fuscus* larvae (Fig. 3). Thus, the data in Fig. 3 capture the known range of body sizes for accurately identified *D. fuscus* larvae, and slightly extend the maximum recorded body length for *D. fuscus* larvae to just over 30 mm.

I also examined a series of Blue Ridge Two-lined Salamander larvae, *Eurycea wilderae*, that I collected from a spring-fed stream in Macon County, North Carolina over a two-year period (1980, 1981). Limb L/W measures on a select number of specimens within the body sizes shown in Fig. 3 were all greater than 2.0, well within the range of the Northern and Southern Two-lined Salamander species. No data for *E. wilderae* are presented in Fig. 3 since I only examined a single breeding population. However, the great similarity that I observed in limb morphology between *E. wilderae*, *E. bislineata*, and *E. cirrigera* larvae suggests that the data in Fig. 3 could be used to distinguish *D. fuscus* larvae from *E. wilderae* where they have syntopic distribution within the Southern Appalachian Mountains. Additional research is needed to determine if the Limb L/W character can be used to distinguish Two-lined Salamander larvae from other members of the "*fuscus*" complex (e.g., *D. conanti*, *D. santeetlah*; see Petranka 1998).

The Limb L/W morphological character can be used to distinguish *D. fuscus* larvae from Two-lined Salamander larvae using digital photographs that clearly show dorsal limb structure. I suggest that the use of photographs for salamander taxonomy would be especially useful for citizens that do not have access to a microscope. For example, color Plate 17-E in Pfingsten and Downs (1989) shows an "old larva" of *D. fuscus* from Ohio. Using a Pickett triangular ruler calibrated to 3/16 graduation, I estimate a Limb L/W = 1.2 for this larva, which is clearly within the regression curve prediction limits for *D. fuscus* (Fig. 3). Conversely, Plate 20-B of Pfingsten and Downs (1989) shows a "young larvae" of *E. bislineata* from Hocking County, Ohio (now *E. cirrigera*), which I estimate has a Limb L/W = 2.0, well within the range of the Southern Two-lined Salamander (Fig. 3). Even if these estimates have a measurement error of 0.2 Limb L/W units, each specimen still would be correctly identified from the photographs alone, without knowledge of body size. Increased use of digital photo-

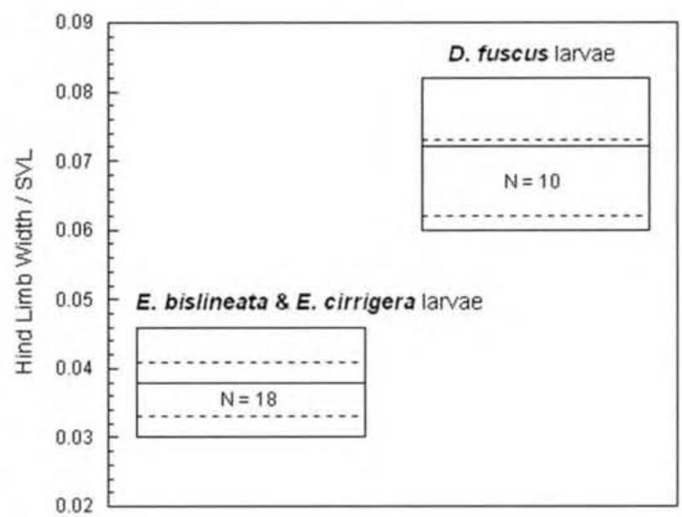

FIG. 4. Frequency plots showing taxonomic separation between Two-lined Salamander larvae and *D. fuscus* larvae using the Hind Limb Width/SVL character. Boxes show range of measurements; solid line represents the median; dotted lines are 25[th] and 75[th] percentile.

graphs taken on live animals for taxonomic purposes would reduce disturbance of local populations by unnecessary collection of numerous voucher specimens, a concern with acknowledged declines in amphibian biodiversity worldwide (Petranka 1998). Bailey (2004) recommends photo-identification for mark-recapture studies with salamanders.

It has been brought to my attention that separation of Two-lined Salamander and *D. fuscus* larva also is obtained by calculation of a ratio (HLW/SVL) of hind limb width (see Fig. 2) vs snout–posterior vent length (Gian Rocco, pers. comm.). The utility of this technique is that it reduces to two the number of required microscopic measurements. One disadvantage is that it cannot be used on photographs of specimens from the dorsal view. However, in lieu of SVL measurement, the approximate location of the vent can be estimated from a digital photograph at a position just posterior to the hind legs (see specimens in Fig. 1) to calculate the ratio.

There are evolutionary reasons why muscular-skeletal differences in limb morphology should be a useful taxonomic character to distinguish larvae of the salamander genera *Eurycea* and *Desmognathus*. As discussed by Duellman and Trueb (1986), obligate stream inhabiting salamander larvae, such as those found in the genus *Eurycea*, use limbs mostly to maintain position in the flowing water medium. Forward movement is more often by use of trunk and tailfin muscles, similar to the undulating motions of a fish. Aquatic locomotion in *Eurycea* larvae also would be aided by buoyancy considerations that tend to mediate the effects of gravity, thus allocation of energy to leg muscle development should be minimal. However, salamander larvae with an affinity to forage in terrestrial microhabitats must have limbs capable of producing forward motion by thrusting the limbs backwards against hard substrate. They also lack the energetic benefits of buoyancy found in a watery medium. Thus, more muscular elements of limbs would be adaptive for *D. fuscus* larvae to compensate for increased force needed for terrestrial locomotion, and may explain the lower Limb L/W ratios for *Desmognathus* compared to *Eurycea* (Fig. 3). It has long been known that newly hatched *D. fuscus* larvae can be found outside the flowing water environment (Wilder 1913), and older *D. fuscus* larvae can burrow in moist sand and fine gravel substrate, well away from flowing water (pers. obs.).

Acknowledgments.—I thank Ralph Pfingsten, Roger Thoma, and Gian Rocco for their comments on the manuscript. John Condit kindly allowed access to voucher specimens at The Ohio State University Museum of Zoology. Paul Anderson, Jim Grow, and Steve Tuckerman helped with field collections. Digital photograph (Fig. 1) was by Hilary M. Duncan, Kent State University, Audio Visual Services.

Mycoplasma Testing of Gopher Tortoises (*Gopherus polyphemus*) in Relation to Military Training Activities at Camp Shelby Training Site, Mississippi

DEBORAH M. EPPERSON
Camp Shelby Field Office, The Nature Conservancy
CSTS-ENV, Building 6678
Camp Shelby, Mississippi 39407, USA

Present address: Department of Interior, Minerals Management Service
1201 Elmwood Park Boulevard, New Orleans, Louisiana 70123, USA
e-mail: deborah.epperson@mms.gov

When the western population of Gopher Tortoises (*Gopherus polyphemus*) was federally listed as "threatened" in 1987, threats included habitat loss, habitat alteration, and illegal taking (USFWS 1987). Upper respiratory tract disease (URTD) is another potentially serious threat that has been identified in many Gopher Tortoise populations throughout the southeast (Diemer Berish et al. 2000). The potential impacts of this disease in wild Gopher Tortoise populations are poorly understood, though significant mortality events that are possibly attributable to URTD have been recorded in some populations in Florida (Gates et al. 2002; McLaughlin 1990; Rabatsky and Blihovde 2002; Seigel et al. 2003).

URTD was first described in Desert Tortoises (*Gopherus agassizii*) in the desert southwest (Jacobson et al. 1991) and is considered a major contributing factor in the decline of Mojave Desert tortoise populations (Lederle et al. 1997). The first documented case of URTD in a wild Gopher Tortoise population was on Sanibel Island, Florida in 1989 (McLaughlin 1990). URTD is a highly infectious respiratory disease caused by a bacterium, *Mycoplasma agassizii* (Brown et al. 1999). The disease is spread through close contact between tortoises (McLaughlin 1997), and males may suffer the highest incidence of mortality, primarily because of differences in activity patterns (Christopher et al. 2003; Gates et al. 2002).

Currently there are three diagnostic tests to detect mycoplasmal infections of Desert and Gopher Tortoises (see Brown et al. 2002 and references therein). They are direct mycoplasmal culture, detection of mycoplasmal chromosomal DNA by polymerase chain reaction (PCR), and detection of anti-*Mycoplasma* antibodies in tortoise plasma by enzyme-linked immunosorbant assay (ELISA). In addition to these diagnostic tests, observations of clinical signs of disease also are frequently used to infer exposure to *M. agassizii* (Schumacher et al. 1997).

The potential long-term impacts of upper respiratory tract disease are unknown. Because of the Gopher Tortoise's protected status, activities that may adversely impact tortoise populations are closely monitored. Previous activities at Camp Shelby Training Site (CSTS) in Mississippi have required tortoise relocations, and the U.S. Fish and Wildlife Service (USFWS) required sampling for URTD before any relocation could occur. The presence of seropositive or suspect tortoises may influence relocation activities (e.g., off-site versus on-site relocation), and in some cases negatively impact military training activities. In 1995, ELISA testing of Gopher Tortoises began at CSTS in association with a relocation project on Range 45. Sampling of 9 individuals resulted in all tortoises either testing positive or suspect for exposure to *M. agassizii* (unpubl. data). Additional opportunistic ELISA sampling (1996–2000; N = 147), prior to the initiation of this study, resulted in 8% of tortoises sampled testing either positive or suspect for exposure to *M. agassizii* (Epperson and Heise 2001). Five of the tortoises opportunistically sampled were from Range 45. Testing of these tortoises resulted in one positive, one suspect, and three negative results. Unfortunately, none of these tortoises was a recapture from the original (1995) Range 45 sampling. Although these data indicate a relatively low percentage of tortoises previously exposed to *M. agassizii*, most of the suspect or positive results (9 of 12) came from tortoises in areas of high military impact (e.g., ranges, firing points). It has been suggested that anthropogenic impacts may cause sufficient physiological stress to trigger outbreaks of URTD in infected populations (McLaughlin et al. 2000). The impacts of tracked vehicles on Gopher Tortoises have been examined at Fort Benning, Georgia (Guyer et al. 1996). They determined that Gopher Tortoise colonies on sites associated with heavy, tracked vehicle maneuvers had an altered demography, as well as altered behavior patterns. Tortoises at these sites were active longer and had to travel farther to forage, potentially exposing them to increased predation risk as well as to physiological stress from increased movements. Testing for exposure to URTD was not part of the Fort Benning study. It is possible that tortoises at CSTS inhabiting areas used for tracked vehicle maneuvers are experiencing similar physiological stressors resulting in a higher prevalence of seropositive or suspect tortoises on these sites. The purpose of this study was to test the hypothesis that tortoises in areas with military training have a higher prevalence of seropositive or suspect ELISA results than tortoises in areas with no military training.

Tortoises were sampled in the summer of 2001 and 2002 in 15 areas of varying military use and habitat type throughout Camp Shelby. Camp Shelby is an Army National Guard training site of approximately 54,270 ha located in Perry, Forrest, and George counties, Mississippi. Three treatments were identified for sampling: ruderal habitat with military activity, ruderal habitat with no military activity, and forested habitat with no military activity. Sites with military activity (N = 6) were selected based on the presence of tracked vehicle maneuvers and resident tortoise colonies. These impacted sites consisted of ranges and firing points and included Range 45, the first site sampled at CSTS in 1995. Sites with no military activity (both ruderal [N = 3] and forested [N = 6]) showed no evidence of tracked vehicle activity, and in some cases were a considerable distance (> 20 km) from any military training activity. Areas without military activity varied from forests to food plots and powerline right-of-ways.

Tortoise burrows at each site were surveyed to determine size class and activity status (Alford 1980; Auffenberg and Franz 1982). Traps were placed at all active and inactive adult burrows. Tortoises were captured by placing a wire live-trap (81 x 25 x 18 cm) at the mouth of the burrow. The trap was shaded with burlap and covered with vegetation to minimize heat stress to trapped tortoises. Traps were checked twice daily. Upon capture, tortoises were evaluated for the presence of clinical signs and a variety of measurements were taken. Tortoises were permanently marked with a unique number by filing a series of notches in the marginal scutes (Cagle 1939). A blood sample was taken from the brachial sinus in the left forelimb. Approximately 0.5 cc of blood was collected and placed into a heparinized vacutainer. In 2001, a subset of tortoises (N = 13) were also sampled using both the culture and PCR diagnostic tests to try to detect the presence of an active *M. agassizii* infection. Nasal lavage samples were collected by flushing each nares with ca. 5 cc of sterile 0.9% NaCl and catching the fluid with a sterile collection cup. All samples (blood and nasal) were placed on ice until they could be transported to the office. All data were collected in the field and tortoises were released within a few hours of capture. Because of the infectious nature of URTD, all equipment was sprayed with a dilute (1:30) bleach solution after every tortoise was handled. All personnel handling tortoises wore rubber gloves and changed gloves before handling another tortoise.

Blood samples were centrifuged to separate the plasma from the red blood cells on the same day collected. Plasma was then drawn off, placed into a separate vial, and frozen. Both plasma and nasal lavage samples were placed into a non-frost free −11°C freezer. At the end of each summer field season, samples were sent to the University of Florida, College of Veterinary Medicine, Mycoplasma Research Lab for analysis. At the Mycoplasma Research Lab, blood samples were tested using an ELISA test to detect the presence of antibodies specific to the causal agent of URTD. Nasal lavage samples were tested using both the mycoplasmal culture and PCR diagnostic techniques as described in

TABLE 1. Summary of Gopher Tortoise ELISA testing for exposure to *M. agassizii* at Camp Shelby Training Site, Mississippi.

Site	Number of Tortoises	Military Use?	Habitat Type	Results
Firing Point 121	10	Yes	Ruderal	1 Suspect
Firing Point 68	11	Yes	Ruderal	Negative
Firing Point 72	11	Yes	Ruderal	Negative
Firing Point 140	10	Yes	Ruderal	Negative
Range 18	8	Yes	Ruderal	Negative
Range 45	4	Yes	Ruderal	1 Suspect
Leaf River WMA	10	No	Ruderal	5 Suspect
Dogwood Lake	8	No	Ruderal	2 Suspect
Ammunition Supply Point	2	No	Ruderal	Negative
T44 East	11	No	Forested	6 Suspect
T44 West	9	No	Forested	2 Suspect
Mars Hill	1	No	Forested	Negative
Cricket's Leap	8	No	Forested	Negative
Guyer	13	No	Forested	Negative
Deep Creek	8	No	Forested	Negative
TOTAL	**124**			**17 Suspect**

Brown et al. (2002). Samples were cultured prior to PCR analysis to increase the sensitivity of the assay. All test results were incorporated into the existing geographic information system (GIS) Gopher Tortoise database and will be used to track disease prevalence and distribution on CSTS.

During the 2001 and 2002 activity seasons (May–August), 124 tortoises were captured at 15 sites (Table 1). The number of tortoises captured at each site varied from 1–13 individuals. Of the 124 tortoises sampled for exposure to *M. agassizii*, there were no positive results; however, 17 tortoises were considered suspect (Table 1). Of the 17 suspect individuals, only two were associated with sites heavily impacted by military training. The remainder came from ruderal and forested sites not impacted by military training (i.e., no tracked vehicle maneuvers). Eight of twenty (40%) of the tortoises tested in Training Area 44 (T-44) had suspect results. Area T-44 is an 890-ha forested site that has been designated as a Gopher Tortoise refuge by the U.S. Forest Service (USFS) and the military. It consists of upland habitats dominated by Longleaf Pine (*Pinus palustris*) and is managed (by the USFS) primarily through prescribed burning. It is considered ideal tortoise habitat, and contains two of the largest Gopher Tortoise populations on Camp Shelby.

Only 16 tortoises exhibited clinical signs referable to URTD. The most common clinical sign observed was palpebral edema and swollen/red conjunctiva; nasal discharge has not been observed at Camp Shelby. The presence/absence of clinical signs did not predict exposure status. Of the tortoises observed with clinical signs, only three had suspect results for exposure to URTD. Similarly, of 17 tortoises with suspect results, only three had any clinical signs of disease. Culture and PCR test results were all negative. Of 13 tortoises tested using culture and PCR, there was only one with a suspect ELISA result and this tortoise had no observable clinical signs of URTD.

No Gopher Tortoises in this study tested positive either for exposure to, or infection by, *M. agassizii*. These data coupled with earlier studies (Epperson and Heise 2001) suggest that URTD is not currently a serious problem at Camp Shelby. Earlier studies in Mississippi (Smith et al. 1998; Thomas and Blankenship 2002) had mixed results. Thomas and Blankenship (2002) conducted an URTD study in association with a relocation project for a gas pipeline (Thomas and Blankenship 2002). They tested 26 tortoises in a five-county construction corridor as well as tortoises in the associated right-of-way. Of those tested, all were seronegative with the exception of one suspect individual that was later re-tested and found to be seronegative. Only one tortoise was observed with clinical signs of URTD, and it was ELISA negative and was later recaptured and no clinical signs were observed. Conversely, sampling of 16 tortoises by Smith et al. (1998) at the Marion County Wildlife Management Area in southern Mississippi resulted in 15 tortoises testing seropositive for exposure to *M. agassizii*. Tortoises were from forested areas open to the public and none exhibited any signs of clinical disease. Overall, these data suggest that URTD is not currently widespread in Mississippi.

McLaughlin et al. (2000) suggest that severe environmental stress (e.g., drought, hurricanes, extreme temperatures, etc.) as well as anthropogenic stress (e.g., habitat loss, relocation, pollution, disturbance) may cause sufficient physiological stress in some tortoise populations to trigger a proliferation of the mycoplasma and a recurrence of clinical signs. Gopher Tortoises are present on 19 military installations in the southeast (Wilson et al. 1997) and it is possible that military activities (i.e., anthropogenic stress) may impact disease prevalence. The potential impacts of military training on Gopher Tortoise populations can be both direct and indirect. Direct impacts include mortality, relocation, and habitat loss. Indirect impacts include habitat alteration/degradation and increased disturbance from training activities. The indirect impacts are harder to quantify as tortoise behavior may be modified in areas where training activities occur (Guyer et al. 1996). The physi-

ological impacts of modified behavior, as well as the associated direct impacts (e.g., pollutants, smoke, noise, etc.) from military activity on a site may act as a source of stress for some tortoise populations. Results from this study suggest no significant relationship between military training and increased exposure prevalence in Gopher Tortoises at Camp Shelby.

To monitor the overall health of a population, repeated sampling of individuals within the population is suggested (Brown et al. 1999). Individual tortoises may have considerable variation in antibody levels, particularly those close to the borderline cut-off values. Changes in the percentages of ELISA positive animals within a population could precede the appearance of clinical disease and provide an early warning of potential disease outbreaks in some populations (Brown et al. 1999). Serological testing is particularly important as URTD is usually clinically silent (i.e., no clinical signs). The data collected in this study, as well as earlier sampling at Camp Shelby, will provide a baseline exposure assessment against which further data can be compared.

Acknowledgments.—I thank the Department of Defense Legacy Program (Project #01-162) and the Mississippi Military Department for funding. Colleen Heise, Jeff Kaminski, Tara Kozlowski, and Brian Mitchell provided field assistance. Camp Shelby Range Control coordinated access to training areas and kept me out of harm's way. The manuscript was greatly improved by the comments of R. Smith and E. Blankenship.

Results of a Herpetological Survey in Ghana and a New Country Record

ADAM D. LEACHÉ
Museum of Vertebrate Zoology, 3101 Valley Life Sciences Building
University of California, Berkeley, California 94720-3140, USA
e-mail: leache@berkeley.edu

The West African country of Ghana has a diverse herpetofaunal assemblage of more than 220 species (Hughes 1988). Ghana is environmentally heterogeneous (Lawson 1968). Although some species have broad distributions, others occur in more specialized vegetative zones (e.g., semi-deciduous forest, coastal thicket, or savannah woodland), offering great potential for studying geographic diversity at varying spatial scales. Myers et al. (2000) identified the Upper Guinean Forest that stretches into Ghana (excluding the Dahomey Gap, an area of savannah woodlands that interrupt the forest) as one of the 25 biodiversity hotspots and conservation priorities on the planet. Thus, it is surprising that Ghana has received so little attention in terms of herpetological research.

Methods

I conducted a herpetological survey of three study sites in Ghana during the dry season from 6–29 March 2003. These survey sites represent savannah woodland, semi-deciduous forest, and coastal thicket vegetative zones as defined by Lawson (1968; Fig. 1). Locality information and habitat descriptions of each survey site are provided in the following sections.

Specimens were found by visual encounter surveys (Heyer et. al. 1994) supplemented with acoustic searching, turning rocks and logs, peeling bark, digging through leaf litter, and excavating burrows. Surveys were conducted during the day and night. Specimens were collected by hand or blowgun (using blunt, plastic plugs as ammunition), and snake tongs were used to capture poisonous snakes. Sex, SVL, tail length, tail condition (complete, regenerated, or broken), weight, date, time, and reproductive condition and habitat (qualitative assessments) were recorded for each specimen. Up to ten individuals of each species were collected at a survey site, and all species encountered are recorded in Table 1. Tissue samples (liver) were flash frozen in liquid nitrogen for future genetic studies. Geographic coordinates for each survey site were determined in the field with a Garmin GPS 72 receiver. Coordinates were recorded as latitude and longitude in decimal degrees, and referenced to the WGS84 (World Geodetic System of 1984) datum. The number series of field tags associated with specimens is ADL 504–825 (Adam D. Leaché, personal field series). Voucher specimens and tissue samples are deposited at the Louisiana State University Museum of Natural Science (voucher specimen catalog series LSUMZ 86813–87134, frozen tissue collection series H20026–H20347).

Survey Sites

Savannah Woodland Site—The savannah woodland site was located in the Northern Region, 2.5 km SW of Buipe by dirt road (08.76877°N, 001.47732°W, 102 m elevation) and surveyed during 6–15 March. Most amphibians collected from this site were found on the margins of one small pond located 1 km N of camp, and the rest were collected along the northern edge of the Black Volta River, 0.5 km S of camp.

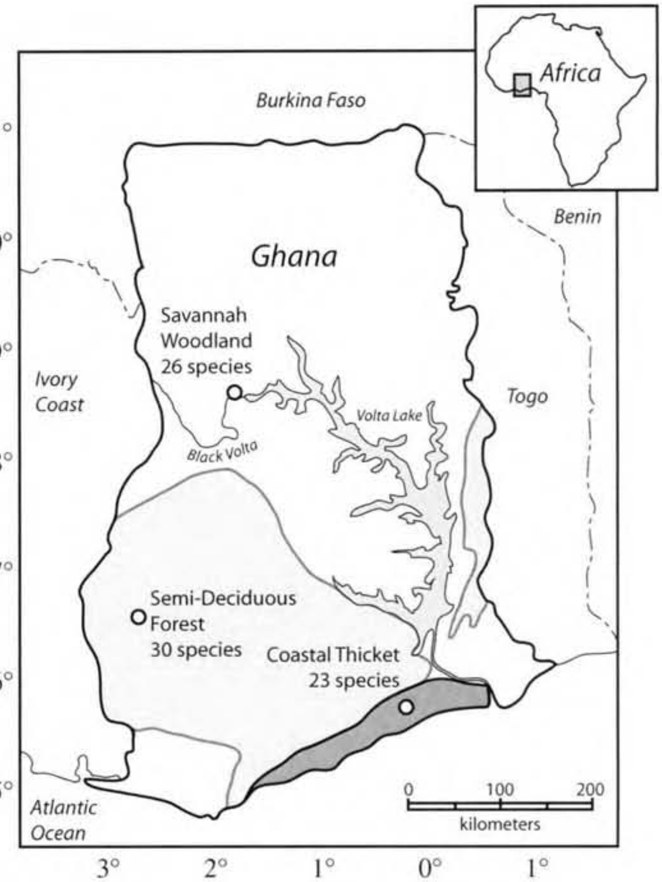

FIG. 1. Maps of Africa (inset) and Ghana (including neighboring countries) illustrating the vegetative zones (Lawson 1968), survey sites (indicated by open circles), and number of species recorded for each survey site.

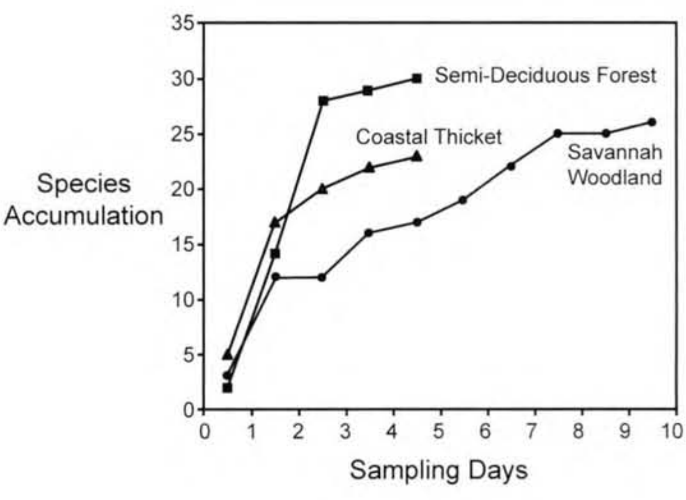

FIG. 2. Species accumulation curves of reptiles and amphibians sampled at the savannah woodland, semi-deciduous forest, and coastal thicket survey sites.

Semi-Deciduous Forest Site—The semi-deciduous forest site was located in the Brong-Ahafo Region, 26 km SW of Goaso (by road to Asumura), along the boundary line between Subim and Ayum Forest Reserves (06.70149°N, 002.07614°W, 101 m elevation) and surveyed during 17–21 March. The site included a mixture of cocoa plantations, urbanized area, and semi-deciduous forest. Although small ponds were present on the margins of the cocoa plantation and urbanized area, forest streams were dry during the survey. The site received a brief rain shower on the evening of 19 March, but it did not result in any water accumulation. Most amphibians were found in disturbed habitats along the margins of the cocoa plantations, but a few were restricted to the semi-deciduous forest

Coastal Thicket Site—The coastal thicket site represents three geographically proximate collecting areas in the Greater Accra Region, 26 km N of Accra, near Amrahia (05.76308°N, 000.10797°W, 87 m elevation), 34 km N of Accra (05.83910°N, 000.10850°W, 62 m elevation), and 55 km NE of Accra, near Nyibena (05.85287°N, 000.25972°E, 44 m elevation). These sites were surveyed during 23–29 March. Small ponds were present at the sites 26 km and 34 km N of Accra and were surveyed during the day and night. These sites received substantial rain on the night of 25 March. The site 55 km NE of Accra was devoid of any water and was only surveyed during the day.

Results

I found relatively equal numbers of species at the survey sites and recorded 26 species in the savannah woodland, 30 in the semi-deciduous forest, and 23 in the coastal thicket. Relatively more anurans were recorded in the semi-deciduous forest and coastal thicket compared to the savannah woodland, and the savannah woodland contained more snakes and turtles (Table 2).

The following LSUMZ specimen represents a new record for Ghana, based on the checklist of the reptiles and amphibians of Ghana (Hughes 1988). Jeff Boundy (Louisiana Department of Wildlife and Fisheries) verified the specimen identification.

Panaspis nimbaensis (Mt. Nimba Snake-Eyed Skink). Brong-Ahafo Region, 26 km SW of Goaso (by road to Asumura), along the boundary line between Subim and Ayum Forest Reserves (06.70149°N, 002.07614°W, 101 m elevation). 18 Mar 2003. LSUMZ 86975, tissue number H-20188, ADL 666. 68 mm SVL, 54 mm tail length (regenerated), 3.7 g. Found in a cocoa plantation adjacent to semi-deciduous forest. Captured by hand under a rotting log surrounded by leaf litter at 1000 h.

Discussion

Only a few surveys have focused on the reptile and amphibian diversity of Ghana. Schiøtz (1964), Leston and Hughes (1968), Raxworthy and Attuquayefio (2000), and Rödel and Agyei (2003) provided detailed information for particular localities and/or taxa, and Hughes (1988) presented a comprehensive checklist for the country. These authors concluded that the herpetological diversity of Ghana is underestimated. Raxworthy and Attuquayefio (2000) surveyed the herpetofaunal community at Muni Lagoon during the peak of the rainy sea-

TABLE 1. Summary of species collected and cumulative species count for each survey site. Numbers refer to specific habitat types and collection localities within the three survey sites (described in the text) and are defined as follows: 1. Savannah woodland, 2. Small pond, 3. Edge of Black Volta River, 4. Semi-deciduous forest, 5. Cocoa plantation, 6. Urbanized area, 7. Small ponds in disturbed areas, 8. Coastal thicket 26 km N of Accra, 9. Coastal thicket 34 km N of Accra, 10. Coastal thicket 55 km NE of Accra. Species collected from new vegetative regions (but not necessarily new habitat types) compared to Hughes (1988) are denoted with an asterisk symbol (*). *Phrynobatrachus* sp. 1 appears to belong to an undescribed species in Rödel (2000).

son and found a maximum of 26 species at a site. Rödel and Agyei (2003) surveyed the amphibians of the Togo-Volta highlands in eastern Ghana and recorded 31 species. Both studies predicted higher species abundance at their study sites based on non-level species accumulation curves and prior collection records. In the present study of the savannah woodland, semi-deciduous forest, and coastal thicket sites, species accumulation curves failed to reach a plateau indicating that additional species remained to be recorded (Fig. 2).

Hughes (1988) provided a checklist of the herpetofauna of Ghana

TABLE 2. Summary of the number of species caught at the savannah woodland, semi-deciduous forest, and coastal thicket survey sites.

	Savannah Woodland	Semi-Deciduous Forest	Coastal Thicket
Frogs	9	15	14
Lizards	8	10	5
Snakes	7	4	3
Turtles	2	1	1
Total	26	30	23

that included undiscovered species, which were inferred to be likely inhabitants of the country. This list included *Panaspis nimbaensis*. This species is distributed throughout Gambia, Guinea, and Ivory Coast, and may have a broader distribution throughout the Upper Guinean Forest. It is likely that surveys of additional rain forest sites in Ghana will further extend the range of this species.

There has not been a rigorous study of the geographic diversity (molecular or morphological) of the widely distributed reptiles and amphibians of Ghana. Candidates for detailed studies of species that potentially occur in high abundance in Ghana include: *Bufo maculatus, B. regularis, Hoplobatrachus occipitalis, Phrynobatrachus accraensis, Ptychadena mascareniensis, P. oxyrhynchus, Agama agama, Hemidactylus brooki*, and *Mabuya affinis*. Additional candidate species occur throughout Ghana, but their low abundance (e.g., snakes) or seasonality (e.g., some anurans and *Chamaeleo gracilis*) make their collection more difficult. In addition, many widely distributed species are able to colonize degraded forest habitats and may be good indicators of habitat degradation (Rödel and Branch 2002; Branch and Rödel 2003). The new collection reported herein provides opportunities for pilot studies on the geographic variation and biodiversity sampling of the Ghanaian herpetofauna.

Acknowledgments.—I thank the Louisiana State University Museum of Natural Science (LSUMNS) for expedition funding. Many thanks to A. M. Leaché and B. Ali for help collecting and preparing specimens, and B. Marks and J. Weckstein for logistical support at LSU and in Ghana. I am especially grateful to J. Boundy for verifying specimen identifications and T. Papenfuss for sharing his knowledge on Ghanaian herpetology. I thank J. Mason of the Nature Conservation Research Center (NCRC) in Accra for support of this survey and help in obtaining collecting permits. I also thank M. Adu-Nsiah of the Ghana Wildlife Division (Forestry Commission) for granting permission to work in these regions, collecting permits, and CITES export certifications. I am grateful to M. Brandley, T. Devitt, R. Diaz, M. Fujita, J. McGuire, T. Mott, and C. Spencer for their comments on the manuscript. W. Branch and C. Raxworthy provided valuable suggestions on an earlier version of the manuscript.

Nest Switching in the Brown Toadlet (*Pseudophryne bibroni*): Do Males Use Chemical Signals?

NICOLA J. MITCHELL*

The view that vocalizations are the dominant form of communication in anuran amphibians has recently been challenged by papers reporting the existence of sexually attractive pheromones in aquatic breeding frogs (Pearl et al. 2000; Wabnitz et al. 1999). Pheromones in fecal pellets deposited on terrestrial substrates serve important roles in territorial defense and courtship in plethodontid salamanders (e.g., Jaeger and Gergits 1979), and in neighbor recognition in the voiceless, archaic frog *Leiopelma hamiltoni* (Lee and Waldman 2002). These and other studies have demonstrated that chemical communication is the most significant factor affecting social behaviors in voiceless amphibians. However, the function of chemosignals in anurans that also communicate acoustically remains enigmatic. Here I report observations of nest switching in a terrestrial breeding anuran, the Australian brown toadlet (*Pseudophryne bibroni*), and speculate that chemical cues may be involved in this behavior.

Pseudophryne toadlets are small, cryptic, terrestrial-breeding anurans characterized by aposematic ventral markings that warn potential predators of their toxicity (Williams et al. 2000; Fig. 1a). Male toadlets call from terrestrial sites that subsequently become flooded by seasonal rains, and mating occurs in subtle soil depressions constructed below leaf litter (e.g., Fig. 1b), or among grass roots or under rocks or logs. Occasionally, males call from discrete burrows, but nest sites are generally difficult to detect unless occupied by a frog or eggs.

During the course of a field experiment conducted in eucalyptus woodland in Watt's Gully Reserve, South Australia (see Mitchell 2001), six males occupied and called from nests that had previously been occupied by another male (Table 1). I was confident that the males that recolonized vacated nest sites were different individuals than the original male because toadlets are distinguishable by their unique ventral markings (Fig. 1a). None of the recolonized nests contained eggs, and the original occupant had vacated the nest up to two weeks before the second male occupied it. In particular, two features of the behavior were remarkable: first, some males moved up to 19 m to occupy a vacated nest (Table 1); and second, in most cases, males were calling from precisely the same location as the previous occupant (i.e., within 2–5 cm). Moreover, all nest sites were concealed beneath 5–15 cm of moist leaf litter, hence visual cues could not have been used to home in on the exact site.

In a separate case, a male toadlet called from a nest site used by another male in the previous breeding season (one year earlier). I was certain of the nest's location because the second occupant sat directly atop a 2 x 2 cm square of chromatography paper that I had inserted at the nest base the previous year during routine measures of nest water potential (the filter was still in place because I had been unable to relocate the nest). This nest was the third occupied by this particular male and was 55 m from the nest he occupied the previous year. The male moved a total of 46 m during the six-week breeding season, and the final nest he occupied was within 15 cm of another male's nest. Importantly, unlike other known cases of nest recycling (e.g., Kluge 1981; Mitchell 2002), nest sites were not obvious, nor were they a limiting resource: leaf litter piles were abundant and male densities were relatively low (between 1 male per 7 m^2 to 1 male per 76 m^2; Mitchell 2001).

While it is possible that males first identified a nest site while a satellite of a calling resident, and subsequently returned to the nest, it appears more likely that a chemical residue gave away the nest's

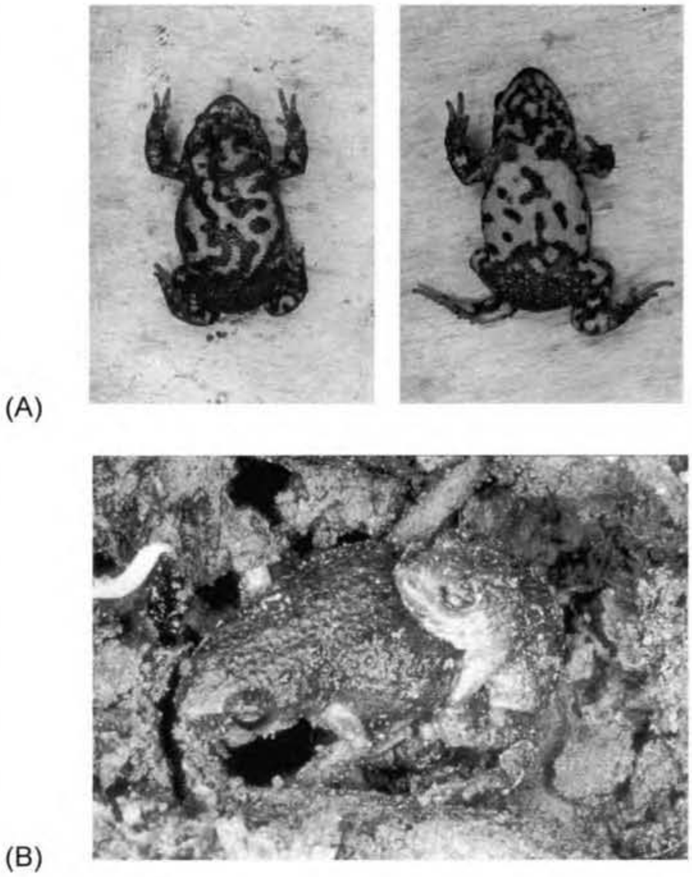

FIG. 1. A) Examples of the ventral markings of *P. bibroni* used for identification of individuals in the study; B) a *P. bibroni* pair in inguinal amplexus. The pair was buried beneath 15 cm of eucalyptus leaf litter, which was removed before the photograph was taken.

Table 1. Six cases where male *Pseudophryne bibroni* occupied a nest vacated by another male.

Nest	1	2	3	4	5	6
First male Identification Code*	98-20	99-M1	98-33	98-44	99-M1	98-8
Number of nights resident in nest	32	unknown	11	2	unknown	unknown
Number of call nights in first nest	13†	1	4†	2	1	1
Eggs in nest?	No	No	No	No	No	No
Second male Identification Code*	99-I1	98-23	99-M1	98-8	99-M3	99-O3
Distance moved from previous nest (m)	17.4	10.0	19.5	11.5	unknown	9.3
Number of nights resident in nest	15	2	12	26	3	1
Number of call nights in nest	13†	1	11†	16†	3	1
Eggs in nest?	No	No	Yes	No	No	No

* Photographs of ventral patterns were used to identify recaptured individuals. The first part of the identification code refers to the year a toadlet was first captured, and the second part to either the order of capture (1998) or an association with an experimental plot (1999 – see Mitchell 2001).

† A proportional estimate of the number of call nights, based on the number of nights during a male's residence that his call effort was monitored (on average, the chorus was monitored every 1–2 nights).

location. Recently, two classes of biologically active alkaloids have been isolated from granular skin glands on the dorsum of *Pseudophryne* toadlets: pumiliotoxins, which occur commonly in other frogs and toads, and pseudophrynamines, which are unique to the genus (Smith et al. 2002). Unusually, the latter compounds are biosynthesized (rather than sequestered from arthropod components of the diet), and *Pseudophryne* toadlets are the only vertebrates known to synthesize alkaloid poisons. These compounds presumably act as an antipredator mechanism, as toadlets are avoided by foraging snakes and have caused rapid death when mouthed (Shine 1987; White 1993).

In addition to dorsal glands, toadlets possess axillary and post-femoral glands that are not found in related genera (Woodruff 1972). These glands excrete copious quantities of odoriferous mucus when stimulated by light anaesthetization with ether; secretions from post-femoral glands are yellow, while secretions from other glands are colorless. Under natural conditions, male toadlets secrete mucus during calling bouts and amplexus, and are more odoriferous than females (M. J. Littlejohn, pers. comm., cited in Woodruff 1972). These observations imply that compounds produced in the skin may have a role in reproductive behaviors, but the chemical composition of these secretions is still to be characterized.

The crawling habit of *Pseudophryne* toadlets is suited to chemosensory communication in that a pheromonal trail is readily followed in complex habitats such as leaf litter where orientation may prove difficult. Male toadlets are thought to leave nest sites during the day to forage (Woodruff 1977), and may utilize chemosignals to return to their nest site. Limited data suggest that peptide pheromones are produced by aquatic amphibians and proteinaceous pheromones by terrestrial species (Houck 1998; Kikuyama et al. 2002; Rollman et al. 1999); certainly the chemicals involved in nest recognition in *Pseudophryne* must have low volatility to persist for such long periods in the field.

How might advertising from a previously vacated nest benefit a male toadlet? *Pseudophryne* toadlets are characterized by polyandrous matings; males may mate with up to three females within a single nest, usually over a period of 1–10 days (Woodruff 1976). In this study, however, recolonizing males were not exploiting a successful oviposition site, rather a subtle depression that had been vacated. A possible benefit to a recolonizing male was that it occupied a site where another male had made a calling investment. As male mating success is correlated with higher call investment (more call nights and higher call rates) in *P. bibroni* (Mitchell 2001), females apparently prefer males with a persistent acoustic signal and hence males may enhance their reproductive fitness by advertising from a nest in which a calling investment has already been made.

Acknowledgments.—The study was funded by the Australian Research Council (grant awarded to R. S. Seymour and J. D. Roberts) and an Australian Postgraduate Award to the author. Forestry South Australia allowed access to the study site, and I especially thank Oliver Berry and Daniel Rogers for assistance with field observations.

Breeding Population Size of an Endemic Litter Frog, *Clinotarsus curtipes*, in the Western Ghats, South India

SAVITHA N. KRISHNA*
and
SHARATH B. KRISHNA
Department of Biosciences, University of Mysore, Hemagangothri Hassan, Karnataka, India, 573220

**Corresponding author; e-mail: savithakn@hotmail.com*

Clinotarsus curtipes is a litter frog endemic to the forests of Western Ghats in the Indian states of Karnataka, Kerala, Tamil Nadu, and southern Madya Pradesh (Daniels 1997; Inger and Dutta 1986). Information on distribution (Dutta 1992), larval hormonal studies (Gramapurohit et al. 2000), and tadpole morphology and their habits (Daniel 2002; Hiragond et al. 2001) have been reported. Breeding occurs in perennial ponds and stream pools. Juveniles and adults forage in nearby canopy- covered forests (Daniel 2002). These frogs can be locally abundant in a particular habitat and might be considered an ideal species for population monitoring. For monitoring, it is essential to establish baseline population data. We examined the population size, survival rates between the successive capture periods, sex ratio and the adult limb deformation in a breeding population in secondary forests of the Western Ghats.

We studied the population biology of *Clinotarsus curtipes* in the Bisale Reserve Forest adjoining the Coorg Hills (12°15'N and 75°33'E), Karnataka State, South India. The study area was on the western slopes of the Western Ghats, ranging from 150–940 m elevation. The area is a tropical rainforest (annual average rainfall 5500 mm) with dense canopy cover and many perennial streams. Our study of breeding ecology and behavioral observations were conducted from May to July 2002 after the area received initial monsoon rains. The study pond was an oval-shaped tank, measuring about 20 m x 40 m. This pond was limited on two sides by a dyke (Fig. 1), on the third side by barren hill base, and on the fourth side by forest. This particular pond was also a breeding site for other frogs inhabiting the area, including *Rana aurantiaca, Rana temporalis*, and *Fejervarya limnocharis*.

A mark-recapture study was conducted at this pond to estimate the breeding population size of *Clinotarsus curtipes*. In order to sample the frogs that arrived at the breeding sites, four 10 x 10 m quadrats were delineated on the banks of the pond using nylon chords (Fig. 1). The sampling quadrats were positioned on all four sides of pond. For mark-recapture efforts five field assistants collected all frogs within each quadrat on 4 occasions, 31 August to 3 September 2002. To allow the frogs to mix thoroughly in the population, a time interval of about 20 h was maintained between each sampling occasion. Captures were uniquely toe-clipped (Donnelly et al. 1994), sexed, and measured (SVL). The recaptures were recorded and released. Individuals of this species are known to be sluggish in movement and were never observed to move by our field disturbances. We analyzed the capture data using the open test model program JOLLY (Hines 1988) for estimating the size of the breeding population.

We observed that these frogs entered and exited the pond from the forest side. The forest was a 40-ha plot with two 4-m wide perennial streams. To estimate the abundance of these frogs in the forest, we placed one 2-m wide by 1080-m long transect line in this forest habitat (Jaeger 1994). The line was positioned in such a way that it transected the entire forest habitat area potentially used by frogs: the transect line began at the pond edge on the forest

TABLE 1. Forest floor anurans sampled during the wet season in the forests of Bisale, Western Ghats, South India.

Species	Number of frogs	Relative abundance (%)
Bufo melanostictus	118	9.37
Indirana beddomii	285	22.65
Fejervarya limnocharis	285	22.65
Philautus sp.	44	3.49
Polypedatus pseudocruciger	3	0.23
Clinotarsus curtipes	450	35.93
Rana temporalis	66	5.24
Rhacophorus malabarica	5	0.39
Total	1258	100.00

side and passed through the forest, perpendicular to the pond edge. A total of 67 transect samplings of forest floor were conducted during the wet season (late May–October). The sampling was done from 0600–0800 h and 1700–2100 h when the species was known to be active.

Our forest floor line transect survey indicated that *Clinotarsus curtipes* was the most abundant species in our study area (35.93% of all captures, Table 1). Adults were found in the litter under forest canopy and moved towards the pond only during the breeding season. Breeding began in July and lasted until September, coinciding with the southwest monsoon season. Males called from diurnal retreats and emerged at the breeding ground on cool (20–21.5°C) and humid nights (relative humidity ca. 95%). A large chorus of litter frogs arrived at the pond for breeding at dusk (1820–1730h) during the breeding season. The juveniles synchronously emerged from the rearing sites during late May to early June and entered the adjoining forests. The newly emerged frogs were 15–18 mm SVL (mean 16.5 ± 2.3 mm; N = 94) and the breeding females grew to a maximum of 68.5 mm SVL (mean 59.19 ± 4.2; N = 38). Male frogs measured 41.6–51.4 mm SVL (mean 46.23 ± 2.3 mm; N = 40).

Our observations were similar to the reports by Daniel (2002). Adults arrived at the breeding sites during the night, emitted calls and were actively engaged in searching for mates. During the day they retreated to mud crevices or rocky hideouts. The total frog count at the breeding site varied from day to day. The closure test performed using the CAPTURE program (Otis et al. 1978) indicated that the breeding population of *C. curtipes* was not closed. It is understandable that there is a back-and-forth daily local movement among adults. Hence, we selected the open model JOLLY for analyzing data that uses daily survival rates for estimating the population size.

We captured 246 frogs and had 46 recaptures during four sampling days at quadrats. No frogs were retained or died during the study. We observed a male-biased sex ratio (6.5 males: 1 female) and 0.8% (2 of 246) limb deformity among the adult *C. curtipes*. The mean breeding population size estimates ranged between 345 and 452 (Table 2). Looking at the goodness-of-fit values, the data seem to fit all the Jolly models. Comparison of the general model (model A with both death and immigration) with the reduced parameter model (model D - constant survival rate per unit time, constant capture probability) showed that the extra parameters of model A are not justified for these data ($\chi^2 = 4.4372$, df = 3, p = 0.2). Therefore, we selected model D as the most parsimonious for the estimation of population size (range 107.97–736.17; mean 422 frogs), where survival and capture probabilities are assumed constant over time (Table 2). The survival rate between each period was 85% and the capture probability was 21%. The mean estimate of marked individuals at each capture period was 81.13 (± 30.54) and the mean number of new individuals arriving at the breeding site during each capturing occasion was 90.26 (± 51.89).

For forest frogs, such as *Clinotarsus curtipes*, vegetation and forest cover are needed for post-breeding dispersal (Osawa and Katsuno 2001). As *C. curtipes* depends on a large water body for breeding, the water source should be maintained in forest habitat for reproduction. The adult feeding grounds are canopy-covered forests where they feed on low flying insects like fruit flies (SNK, pers. observ.). We observed adults and juveniles entering and exiting the pond from the forested side. Thus, proximity of a breeding site to forest appears important for this frog. In the case of the forest frogs *Rana japonica* and *R. ornativentris* in Tama Hills, Japan, the dispersal was within 500 m of the breeding site and hence, a wide forest patch in a radius of about 300 m was recommended to be preserved for those species (Osawa and Katsuno 2001). Although we do not know the exact distance traveled by *C. curtipes* from the spawning ground, we have captured them at the maximum distance of 1008 m away from the breeding site. From our observations, we suggest that for such forest frogs, it is not only necessary to conserve a water source for breeding but also the forest habitats for their non-breeding activities and survival. Long term monitoring is required to study population fluctuations and the effect of human disturbance on their feeding habitat and the breeding sites. One of the major causes of anuran population decline around the globe is habitat destruction (Richards et al. 1993). Therefore it can be hypothesized that the habitat de-

TABLE 2. Goodness of fit test value and the estimated population size (N) for a breeding population of *Clinotarsus curtipes* at a pond in Bisale, Western Ghats, India. PHI is the survival rate between the sampling occasions, P is capture probability, M is the estimated number of recaptures and B is the estimated number of new captures.

Parameter	Chi-square (df)	p	PHI%(SE)	P% (SE)	M (SE)	B (SE)	N (SE)	95% CI
Model A	1.30 (3)	0.72	93.44 (16.35)	24.18 (12.84)	56.66 (11.89)	162.53	345.15 (86.80)	175.01–515.28
Model D	5.73 (6)	0.45	85.45 (11.82)	21.31 (4.6)	81.13 (30.54)	90.26 (51.89)	422.07 (160.25)	107.97–736.17
Model B	2.77 (4)	0.59	94.86 (17.16)	21.89 (0.55)	97.01 (45)	169.36 (78.23)	452.64 (210.71)	39.64–865.63

struction as a result of water diversion projects and pipelines in these forested areas would impact the breeding sites and the canopy covers that are vital for *C. curtipes* survival. Long-term demographic assessments are important because they provide quantitative measures to assess status and trends to guide management of species and habitats in these forests.

Acknowledgments.—We thank the Forest Department, Bisale Reserve Forest for their support in conducting the field observations. We thank Venkatesh and Anil for their field assistance and G. Umesh for allowing us to use their estate cottage during the studies Our thanks are due to James E. Hines for his valuable statistical suggestions. We thank Indraneil Das and an anonymous reviewer for their valuable comments on the earlier manuscript. The fieldwork was facilitated by DAPTF seed grants 2001, funding to the first author.

Although uncommon, anuran species with semi-terrestrial larvae have evolved independently in at least six anuran lineages. In all cases the species have very restricted ranges. Survival of some of these species may ultimately depend on captive breeding programs. However, standard methods for raising terrestrial tadpoles have not been established.

We raised semi-terrestrial tadpoles of *Nannophrys ceylonensis*, a threatened ranid frog endemic to Sri Lanka (Bambaradeniya and Samarasekara 2001). We investigated the growth conditions and intraspecific interactions of these tadpoles, including interference competition and cannibalism. We describe larval feeding behavior on various types of food and document differences in microhabitat use among tadpoles at different stages and sizes in the laboratory. We also report on aspects of egg hatching in the laboratory. To our knowledge this is the first account of rearing semi-terrestrial tadpoles under artificial conditions.

Nannophrys ceylonensis is found in restricted locations in the lowland wet zone of Sri Lanka. We collected 42 eggs and 68 tadpoles (Gosner stages 25–45; Gosner 1960) of *N. ceylonensis* from exposed, vertical, wet rock surfaces within a mixed secondary forest close to the Man and Biosphere Reserve at Labugama (06°51'N, 80°11'E; 150 m elev.) and Waga (06°54'N, 80°07'E; 140 m elev.) in Colombo District.

Eggs and tadpoles of *N. ceylonensis* are most abundant during the rainy season (May–June and October–December), and we collected the eggs and tadpoles during this time. We used two dry leaves to gently lift tadpoles and eggs from the rock and transported them to our laboratory at the Department of Zoology, University of Colombo, in containers with a thin film of water (2–3 mm) and some moss collected from the rocks.

Tadpoles and eggs were housed in glass tanks (35 cm long x 16 cm wide x 20 cm high) covered with nylon mesh to exclude insects. About 30 ml of aged tap water were added to each tank

housing tadpoles. Every two days, 75% of the water was removed and replaced with fresh aged water. The tanks were kept at an angle of 20–30°, such that the water accumulated at one end (maximum depth: 5–6 cm), leaving the other end dry. Tadpoles kept without water showed stress behaviors within 2–3 min, such as abnormal writhing movements and jumping. This is an unusual behavior for these tadpoles in the laboratory but similar to their escape response when attacked by predators in the field. Stones (height 5–7 cm, surface area 40–45 cm^2) were brought from the field sites, and one was placed in the water in each tank to provide hiding and perching spots for the tadpoles. We also added pieces of twigs, aquatic macrophytes, and pieces of clay pots for the same purposes. In the tanks housing eggs, the eggs were placed on top of wet moss.

The tanks were placed next to windows to maintain a natural photoperiod. The temperature and relative humidity in the laboratory simulated natural conditions, and ranged from 27–31°C and 74–82% respectively.

Cannibalism and tadpole density.—High larval density is known to increase aggressive interactions among amphibian larvae (Reques and Tejedo 1996), such as biting behavior (Summers and Symula 2001) and cannibalism (Nyman et al. 1993; Summers and Symula 2001). In a pilot experiment, we stocked two tanks with seven tadpoles (all Gosner stage > 37) each. After two days, two tadpoles from one tank and three from the other had been cannibalized. The larger, more active tadpoles preyed on the smaller and less active ones (N = 5, predator snout–vent length [SVL] range: 7.3–7.9 mm, prey size range: 6.0–6.2 mm SVL). The predatory tadpoles typically directed their attacks first at the smaller individuals' tail tip. Once a considerable part of the tail was eaten, the smaller tadpoles were immobilized and became increasingly vulnerable to attack. Tadpoles with damaged tail tips also were observed in their natural habitats.

After the pilot experiment, we adjusted the number of tadpoles housed in each tank according to developmental stage: 1) young larvae (Gosner stages 25–31, three individuals in each of 7 tanks); 2) "mature" larvae (Gosner stages 32–40, three tadpoles in each of 7 tanks); and 3) metamorphic individuals (Gosner stages 41–45, three tadpoles in each of 4 tanks). Our observations of dietary preference, intraspecific competition, and microhabitat use for these tadpoles were made concurrently over 10 consecutive days.

Dietary preference.—We presented the tadpoles with ten different foods: powdered commercial dog food pellets, powdered fish meal, yeast suspension, raw chicken liver, live *Tubifex* worms, boiled egg yolk, boiled *Amarantus* leaves, powdered dried fish, powdered dried shrimp, and algae scraped from rocks in the natural habitat. Only one food was presented to the tadpoles at a time. Feeding behavior involved three consecutive stages: 1) *orientation*—movement towards the place where the food was added; 2) *contact*—the contact of the tadpole's snout with food particles (usually occurring within 3–5 sec of orientation), and 3) *ingestion*—taking food into the buccal cavity by movements of the jaws. Feeding (i.e., orientation, contact, and occasionally ingestion) lasted 15–75 sec in duration, and occurred in discontinuous bouts. The duration of feeding bouts was independent of the quantity of food available; feeding was intermittent even when excess food was present. Three food items (raw chicken liver, *Tubifex* worms, and boiled egg yolk) elicited orientation and contact, but were not ingested. Dog food, powdered fish meal, yeast suspension, boiled *Amarantus*, and powdered dry fish never stimulated orientation or contact. Only two items, algae and powdered shrimp, were readily eaten by tadpoles at all larval stages.

The most effective food for tadpole growth was powdered dried shrimp. Fresh shrimps were oven dried for 12 h and then ground with a mortar and pestle. This powder was passed through a mesh sieve to separate the finer particles (< 2.5 mm), which were kept in an airtight container to prevent rehydration and decomposition. Maximum growth was achieved when every two days an amount of shrimp powder, about 5–10% of the body weight of the tadpoles, was mixed with a few drops of aged water and placed at the higher end of the tank, right at the glass-water interface. Uneaten particles were removed from the tank after 30 min to avoid polluting the water. Once a month the shrimp powder was supplemented with a pinch (i.e., 2–5 mg) of multi-vitamin powder (Unical Multi-Vitamin Powder, Unical Ltd., [Ceylon] Sri Lanka).

If the food floated on the water surface, the tadpoles did not eat it. Tadpoles of all stages scraped the surface of the tank and the stone with their beaks, presumably in search of food, but the most food was eaten at the shallow border between the water and tank bottom.

Relatively little information is available on the natural diets of tadpoles (Hoff et al. 1999) and none is known for semi-terrestrial tadpoles. In their natural habitat *Nannophrys* larvae eat algae, mosses, and microscopic animals that are found on the rocks (Wickramasinghe, pers. obs.). However, later stage larvae also consume more rotifers, nematodes, and microscopic arthropods than do younger tadpoles.

The size of the food particles plays a major role in tadpole foraging. Seixas et al. (1998) reported that a particular food particle size (0.5 mm) resulted in the best tadpole growth in *Rana catesbeiana* larvae. We found that *N. ceylonensis* tadpoles, which are one to two orders of magnitude smaller than *R. catesbeiana* larvae, appeared to prefer particles < 2.5 mm.

Intraspecific competition.—Larger tadpoles (Gosner stage = 32) displayed dominance during feeding. If the tadpoles in one tank were of disparate sizes, the larger individuals were the first to approach the food. Individual tadpoles would curl their tail around a food patch, thereby preventing access to the food by smaller tadpoles. The tadpoles did not exhibit this circling behavior in the absence of other tadpoles. At least 3–4 min after the larger tadpoles finished eating the small ones were able to approach the food. However, when food was placed at more sites than there were tadpoles the smaller tadpoles faced no opposition to food access from larger conspecifics.

Wassersug (1975) reported that successful competition for food was directly related to the size of tadpoles; large tadpoles often dominated smaller ones when feeding. Savage (1961) reported foraging dominance of larger *Bufo bufo* tadpoles over smaller conspecifics in a pond. Similarly, in *R. catesbeiana*, smaller tadpoles were displaced by larger tadpoles in captivity when provided concentrated non-planktivorous food (Flores-Nava and Vera-Muñoz 1999). The larger tadpoles in that study "guarded" food by continuous movements around the food patches, thus keeping food out of reach of the smaller individuals. A similar behavior was shown by tadpoles of *Limnonectes kirtisinghei* in the laboratory (Wickramasinghe et al. 2001). We also observed the food circling

behavior of larger *N. ceylonensis* tadpoles in their natural environment.

Microhabitat use.—One of the purposes of our experiment was to determine the location (i.e., the microhabitat) in the tank preferred by the tadpoles for resting. On each study day, all three tadpoles in each tank were observed for a 2-minute period followed by another 2 minutes 45 minutes later. If any tadpole spent more than 75% of the 2-min observation period at a single location in the tank, this was recorded as the preferred resting microhabitat for that tadpole.

Microhabitat preference for tadpoles that moved continuously during the observation period was not recorded. For each developmental group the total number of tadpoles that rested in each tank position was summed and averaged. These numbers were then averaged over the 10-day study period (Table 1).

TABLE 1. Microhabitat selection by three developmental groups of *Nannophrys ceylonensis* tadpoles observed at two time intervals. Those tadpoles that moved continuously during the 2-min observation period are not included. Ratios in parenthesis represent the number of resting tadpoles out of the total number of tadpoles in all tanks.

Developmental Group (Gosner stage)	At time zero	After 45 min
Young (25–31)	Under a pebble (17/21)	Under a pebble (11/21)
"Mature" (32–40)	At tank-water interface (16/21)	Under a pebble (11/21) and at the tank-water interface (10/21)
Metamorphic (41–45)	At tank-water interface (10/12)	At tank-water interface (12/12)

The most common resting position was either under the submerged pebble or at the shallow tank-water interface. Tadpoles were not found on the pebbles. In the initial observation period, at time 0, some tadpoles from each developmental group were continuously moving; however, after 45 min all tadpoles post stage 32 and metamorphosing individuals were found resting. Microhabitat use by anuran larvae that changes with their growth, development and habitat quality has been reported for other species (Alford 1986; Schley et al. 1998; Vences et al. 2000). Aquatic tadpoles typically select a preferred position in the water column (e.g., Eterovick and Sazima 2001), but stationary *N. ceylonensis* tadpoles were always in contact with surfaces. Tadpoles in our experiment selected different microhabitats in the laboratory depending on their developmental stage. Tadpoles below stage 32 preferred hiding under the pebble, whereas more developmentally advanced tadpoles were found exposed to the air at the shallow end of the tank. Half of the tadpoles in the Gosner stage 32–40 group also were found under the pebbles after 45 minutes.

Observations of tadpoles in their natural environment suggested similar stage-specific patterns of microhabitat use. In general, larvae below stage 24 remained in their nest, a rock crevice guarded by the father (Wickramasinghe et al., *in press*). Usually tadpoles of stages 24–32 also remained in close proximity (range 15–75 cm) to their nest, and tadpoles older than stage 32 moved as far as 1.7 m from their nest onto exposed rock surfaces.

Tadpoles hatched in the laboratory.—Tadpoles hatched at stage 21 from the eggs collected in the field after at least two days in the laboratory. They generally started feeding at stage 25. The total time from hatching to metamorphosis in captivity was 51–60 days. In general, excluding the cannibalism at high density, the tadpoles we collected from the field all remained in good health in the laboratory with the exception of four individuals in a single tank that died two days after the end of the experiment. These tadpoles were lethargic and did not eat the day before they died. After death, they appeared externally normal, but microscopic examination revealed fungal hyphae on their body surfaces.

In conclusion, semi-terrestrial tadpoles of *Nannophrys ceylonensis* can be raised until metamorphosis and eggs can be hatched successfully in a laboratory. A diet high in animal protein appears to be best for these larvae, consistent with dietary analysis of field collected individuals. Given the highly convergent ecology and morphology of semi-terrestrial tadpoles from around the world we are optimistic that a similar diet could be used to raise semi-terrestrial tadpoles of other species and genera.

Acknowledgments.—We thank Ananda Wijaya for field assistance and Ross Alford, Ron Altig, Marty Crump, Greg Handrigan, Jon Loman, Lesley Roberts, Luis Schiesari, Bruno Viertel, and Sari Zelenietz for constructive criticism on draft manuscripts. A grant from the University of Colombo to DDW and a Natural Sciences and Engineering Research Council of Canada award to RJW supported this study.

Lotic ecosystems are increasingly viewed as having three interactive spatial compartments, i.e., channel sediments, the hyporheic zone, and flood plains or riparian areas (Cummins et al. 1983; Ward 1989). The hyporheic zone is the sub-benthic habitat of interstitial spaces between substrate particles in the stream bed, and is the transition zone between surface flow and ground water (Boulton et al. 1998; Stanford and Ward 1988; White 1993). Extensive use of the hyporheic zone by invertebrates has been reported (Smock et al. 1992; Williams and Hynes 1974), but aside from several accounts of nesting in the hyporheic zone (e.g., Dethlefsen 1948; Henry and Twitty 1940), little is known about amphibian use of this habitat. The objective of this paper is to describe incidental captures of Pacific Giant Salamander (*Dicamptodon tenebrosus*) larvae within the hyporheic zone of two seasonally intermittent streams while sampling for macroinvertebrates in the Prairie Creek Redwoods State Park, Humboldt County, California.

We conducted the study in two small intermittent tributaries of Godwood Creek that drain relatively undisturbed late seral redwood forest (*Sequoia sempervirens*), within 1 km of each other. We sampled lower, middle, and upper reaches in each tributary. Streambed substrate included significant river deposits of Klamath origin (Dolezel 1974), consisting of a range of particle sizes from sand (0.06–2.0 mm) and gravel (2.0–32.0 mm) to pebble (32.0–64.0 mm), cobble (64.0–256 mm) and boulder (> 256 mm). However, smaller particle sizes (sand and gravel) tended to dominate the substrate, particularly in the lower gradient reaches of these tributaries. Lower basin sample points were located as close to the confluence with Godwood Creek as was practical while assuring that they were several meters upstream from Godwood Creek's bank full winter flow. Each was ca. 10 m from the confluence. Upper basin sample points were chosen by walking both tributary channels in late July 1999 and selecting sites at the extreme upper limits of the mid-summer surface flow. Middle basin sample points were located approximately midway between the upper and lower sample points. Upper and lower sample points were ca. 400 m apart with an estimated 100 m elevation change. Total stream reach length was ca. 600 m.

At each sample point hyporheic well traps were constructed of 10-cm diameter PVC, cut at 1 m or 1.6 m lengths. One-meter traps were used to sample the hyporheic zone from 0 to -30 cm beneath the streambed, and 1.6 m traps were used to sample from -30 to -60 cm deep. Each trap had a perforated region of 1-cm diameter holes drilled at 2-cm intervals beginning 4 cm from the bottom (Fig. 1). The perforated region extended 30 cm, with one vertical row of holes in each quadrant around the pipe. The holes allowed hyporheic fauna to enter the trap from upstream, downstream, or lateral directions. The unperforated chamber at the bottom of each pipe provided a holding area for trapped animals. The bottom of each pipe was permanently capped to prevent the loss of captured animals. A removable cap on the above ground top of each trap prevented the entrance of terrestrial animals and debris.

One 0 to -30 cm trap and one -30 to -60 cm trap (Fig. 1) were deployed at each of the sampling points in the upper, middle, and lower region of both intermittent tributaries. Shallow well traps were placed so that the first trap entry hole was positioned ca. 3 cm below the streambed. Traps were allowed to fill with water and were pumped out repeatedly to remove mud that entered through the perforations during placement and backfilling. The traps were allowed to equilibrate *in situ* for six weeks before the first samples were collected. Samples were then collected from the traps once every six weeks for 62 weeks, from July 1999 to October 2000, for a total of 102 samples. Trapped macroinvertebrates and *D. tenebrosus* were removed from the wells with a 7.6 cm diameter Beckson utility hand pump. Six-liter samples were pumped from each trap to insure standardization of sample volume.

We found individual larval *D. tenebrosus* in 22 samples. Fifteen larvae were captured in the 0 to -30 cm traps and seven in the -30 to -60 cm traps. Larvae ranged from 39–83 mm total length (mean $\pm$ SE = 55.2 $\pm$ 2.6 mm). Similar numbers of salamanders were captured in each tributary, and captures occurred throughout the year and did not appear to vary with season. *D. tenebrosus* were captured in all three stream locations, although more were captured at the lower sites (9) than in the middle (7) or upper (6) sites. All *D. tenebrosus* captures occurred when surface flow was < 4 cm deep, and the majority of captures (18 of 22) occurred when there was no surface flow.

Larval *D. tenebrosus* might use hyporeic zones to forage, escape predation, or as refuge from declining surface flows. Our captures might have been limited to small larvae by the pore size of our traps, and larger *Dicamptodon* may use hyporheic habitats for other activities such as nesting (Dethlefsen 1948; Henry and

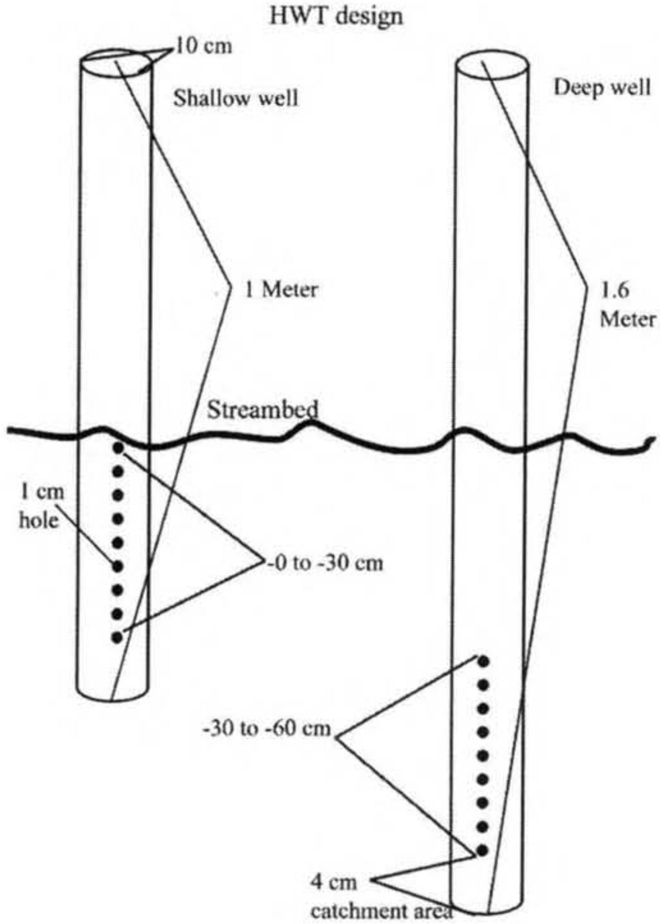

FIG. 1. Diagram of the hyporheic well traps for invertebrates designed for this study. Construction material was 10 cm diameter PVC pipe, permanently capped at the bottom and with a removable cap at the top to allow access for sampling.

Twitty 1940; Nussbaum 1969).

Our observations suggest that hyporheic zones might provide important and not previously recognized habitats for amphibians in intermittent headwater streams. Additional sampling is needed to better characterize hyporheic use by *Dicamptodon* and other stream amphibians such as the torrent salamanders (*Rhyacotriton* spp.). Better information notwithstanding, management regulations throughout the Pacific Northwest, particularly forestry protections for low order (headwater) stream courses, should include protections for these important spatially and temporally subterranean aquatic environments that are currently either unprotected or weakly protected (see Sheridan and Olson 2003).

Determining the nature and extent of bufonid movements is critical to understanding the autecology of each species, as well as to developing effective conservation strategies. Within many toad (*Bufo* spp.) populations, individuals must migrate considerable distances to reach habitats essential for fulfilling requirements that change seasonally and ontogenically (deMaynadier and Hunter 2000; Sinsch 1990). Summer home range movements (*sensu* deMaynadier and Hunter 2000) are often necessary to allow individuals to meet multiple resource needs (e.g., food and thermoregulation sites; Zug et al. 2001). Documenting movement patterns helps biologists determine the nature, timing, spatial extent, and distribution of habitat use by a species. Moreover, understanding movements can be essential to predicting the population-level effects of some ecosystem alterations (e.g., habitat alteration, creation of barriers to movements, or introduction of predators along

travel corridors) and to planning habitat restoration that will conserve toad populations. Boreal Toads (*Bufo boreas boreas*) are declining throughout much of their range in western North America (Corn 2000); documenting their movement patterns may prove integral to understanding and arresting the declines.

Studies of toad movements often have documented long seasonal migrations and very limited summer home range movements, but the studies have focused on terrestrial travel and have not explored distances moved in aquatic habitats. Toads of many species make extensive movements, the longest are typically migrations up to several kilometers among spring breeding areas, summer foraging areas, and overwintering sites (deMaynadier and Hunter 2000; Kusano et al. 1995; Miaud et al. 2000; Sinsch 1988, 1990, 1992). Post-breeding movements within summer home ranges typically are restricted to several hundred meters (deMaynadier and Hunter 2000; Kusano et al. 1995; Sinsch 1988, 1990, 1992).

Several studies indicate that Boreal Toads, like other toad species, sometimes make long seasonal migrations (0.9–2.4 km; Bartelt 2000; Campbell 1970a; Muths 2003), but make considerably shorter summer home range movements (Campbell 1970b). Although metamorphosed Boreal Toads are considered "largely terrestrial" except during the breeding season (Nussbaum et al. 1983), they do occur along the edges of rivers and streams (Carpenter 1954; Olson et al. 1997; Robinson et al. 1998). Evaluating Boreal Toad travel via streams could enhance our understanding of home range size, dispersal distances and routes, and the effects of disturbance on dispersal (McGee et al. 2002). We evaluated instream movements in northern Rocky Mountain populations of Boreal Toads. Our objectives were to determine the prevalence, distance, and diel timing of summer movements by juvenile and adult Boreal Toads in three western Montana streams.

Materials and Methods.—In Summer 2001, we studied Boreal Toad movements in Chamberlain Creek, a second-order perennial tributary to the Blackfoot River, Powell County, Montana, draining 87.2 km^2 (Fig. 1). The study segment had channel slopes of 1.5–2.0%, a mean wetted width of 4.1 m, substrate dominated by gravel and cobble (2–64 and 64–256 mm diameter, respectively), and an elevation of 1180 m at its mouth. During the study, mean discharge was 0.09 m^3/s, and maximum water temperature was 17.3°C.

In Summer 2002, we studied movements in Little Blue Joint and Slate creeks, second-order streams in the West Fork Bitterroot River basin, Ravalli County, Montana (Fig. 1). Little Blue Joint Creek had a mean wetted width of 3.2 m, mean channel slope of 3.2%, median substrate particle size of 36 mm, and elevation of 1449 m at its mouth. The riparian zone adjacent to the study reaches in Little Blue Joint Creek burned in Summer 2000, but contained abundant coarse woody debris and lush regrowth of forbs and grasses in 2002. Slate Creek had a mean wetted width of 6.3 m, mean channel slope of 2.2%, median substrate particle size of 41 mm, and elevation of 1441 m at its mouth. Mature conifers and deciduous shrubs bordered the Slate Creek study reaches. Maximum water temperatures during the study were 17.9°C in Little Blue Joint Creek and 14.1°C in Slate Creek.

In both years, we captured Boreal Toads in streams using two-way weirs made of two hoop nets facing opposite directions that were connected to each other and to both banks by leads (0.5–4.0 m long). Hoop nets, constructed of multifilament nylon netting (0.6-cm bar length), were 2.0 m long. Minimum diameters of the funnels were 4.0–7.5 cm, and hoop diameters ranged from 30 to 38 cm, depending on stream size. We refer to the hoop nets that captured animals moving downstream as "downstream traps."

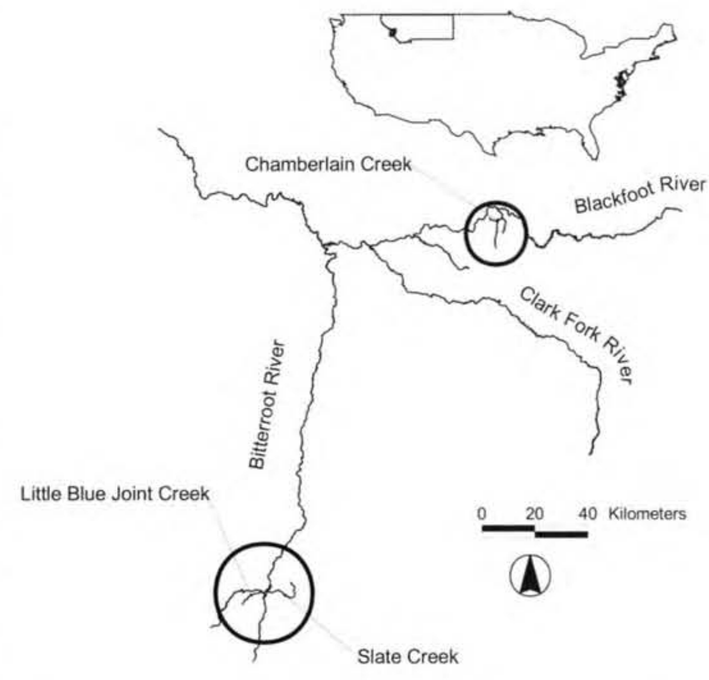

FIG. 1. Locations of the three study streams (circles) in western Montana, USA.

We operated the weirs in Chamberlain Creek from 23 July to 16 August 2001, except for 24 h beginning on 1 August during high stream flows. We divided the study segment into upper and lower sections, separated by a nonoperating, low-head diversion dam. On 23 July, we installed six two-way weirs, spaced 8–114 m apart (at least two riffle-pool sequences), in the upper section (Schmetterling and Adams 2004). On 30 July, we moved three of the weirs to the lower section and spaced them 16–18 m apart (one riffle-pool sequence). Three weirs in the upper section remained in place, so after 30 July, the six weirs encompassed 1.6 km of the creek. In all streams, we chose weir locations based on fish distributions and habitat features, but not on toad distributions.

During summer 2002, we operated eight weirs in both Little Blue Joint (11 July–16 August) and Slate (16 July–16 August) creeks. Spacing between weirs ranged from 185 to 2496 m, and weirs enclosed 4.5 km of Little Blue Joint Creek and 3.1 km of Slate Creek.

We checked all traps at least daily (except 5 August 2002), counted all and measured most boreal toads (snout–vent length, SVL) on a measuring board, and released toads in the direction they were moving when captured. To distinguish nocturnal or crepuscular from diurnal movements, we checked traps in mornings and evenings from 24 July to 1 August 2001 in Chamberlain Creek.

We distinguished juvenile from adult toads a posteriori based

[b]One toad was not measured and is not included in counts.
[c]Includes one toad that was not measured but was known to be an adult.

on length. Length-frequency histograms showed two distinct groups; therefore, we classified toads < 55 mm SVL as juveniles and larger individuals as adults (Table 1; consistent with Nussbaum et al. 1983; Olson et al. 1986).

We marked adult toads with visible implant elastomer or acrylic paint on the ventral side of the mandible; most juvenile toads were too small to mark using this method. Although marks were unique to weirs, not individuals, we distinguished among marked individuals via a combination of marks, capture date, and SVL. In Chamberlain Creek, we marked all adult toads, beginning on the third day of trapping. In Little Blue Joint and Slate creeks, although we recorded captures and measured toads daily at all traps, we marked toads on only four days (Table 2) and at four traps in each stream. The four traps were each 195–607 m from neighboring traps and included the upstream-most trap on both streams. We checked toads for previous marks at all traps on four days (Table 2). Thus, the sample sizes for mark-recapture data were much smaller than for frequency-of-capture data in Little Blue Joint and Slate creeks.

We used capture data to describe the frequency and temporal patterns of toad movements in streams and to determine the ratio of juvenile to adult captures. We used linear regression to test for temporal trends in the number of captures of juvenile and adult toads in Little Blue Joint and Slate creeks. We used mark-recapture data to characterize the distances and directions moved by individual adult toads in all three streams. "Net movement" is the distance between the most distant captures for an individual.

Results.—We observed frequent movement by Boreal Toads in all streams. We made 252 captures (70 juveniles, 181 adults, 1 unknown; Table 1), all in downstream traps, and captured some toads more than once (e.g., see Table 3). During the eight days of diel movement comparisons in Chamberlain Creek, all six Boreal Toad captures (all adults) were made during night or twilight.

Recaptures of marked toads indicated that some adult toads moved hundreds of meters during both summers and in all three streams, although most recaptures were from Chamberlain and Slate creeks (Table 3). In Chamberlain Creek, we recaptured 5 of 11 marked toads, and the median net distance moved by recaptured individuals was 294 m (median daily movement, 73 m). In Little Blue Joint and Slate creeks, we recaptured 7 of 18 marked toads, and median distance moved was 353 m (median daily movement, 71 m). Two juvenile toads were marked, but neither was recaptured.

Toads traveled both up- and downstream, but downstream movements predominated. Although all recaptures were made in downstream traps, four recaptured toads had traveled upstream, bypassing weirs. The longest movement we documented (1.5 km in 6 days) was directed upstream, and the toad bypassed four weirs. In addition, at least two toads bypassed a weir while moving downstream.

The ratio of juvenile to adult toads captured varied among streams (Table 1, Fig. 2). We did not capture any juvenile toads in Chamberlain Creek. The proportion of juvenile-to-adult toad captures differed significantly between Little Blue Joint and Slate creeks, even when we restricted analysis to captures made during the same time period (15 July–15 August, $\chi^2 = 14.04$, $P < 0.001$). Although the numbers of juvenile toad captures made after 15 July were similar between the two streams, about three-fold more adult captures were made in Slate Creek.

TABLE 2. Number of Boreal Toads marked and recaptured by date in three western Montana streams. Number of recaptures includes repeat recaptures of the same individual, whereas cumulative number recaptured includes only the number of unique individuals recaptured.

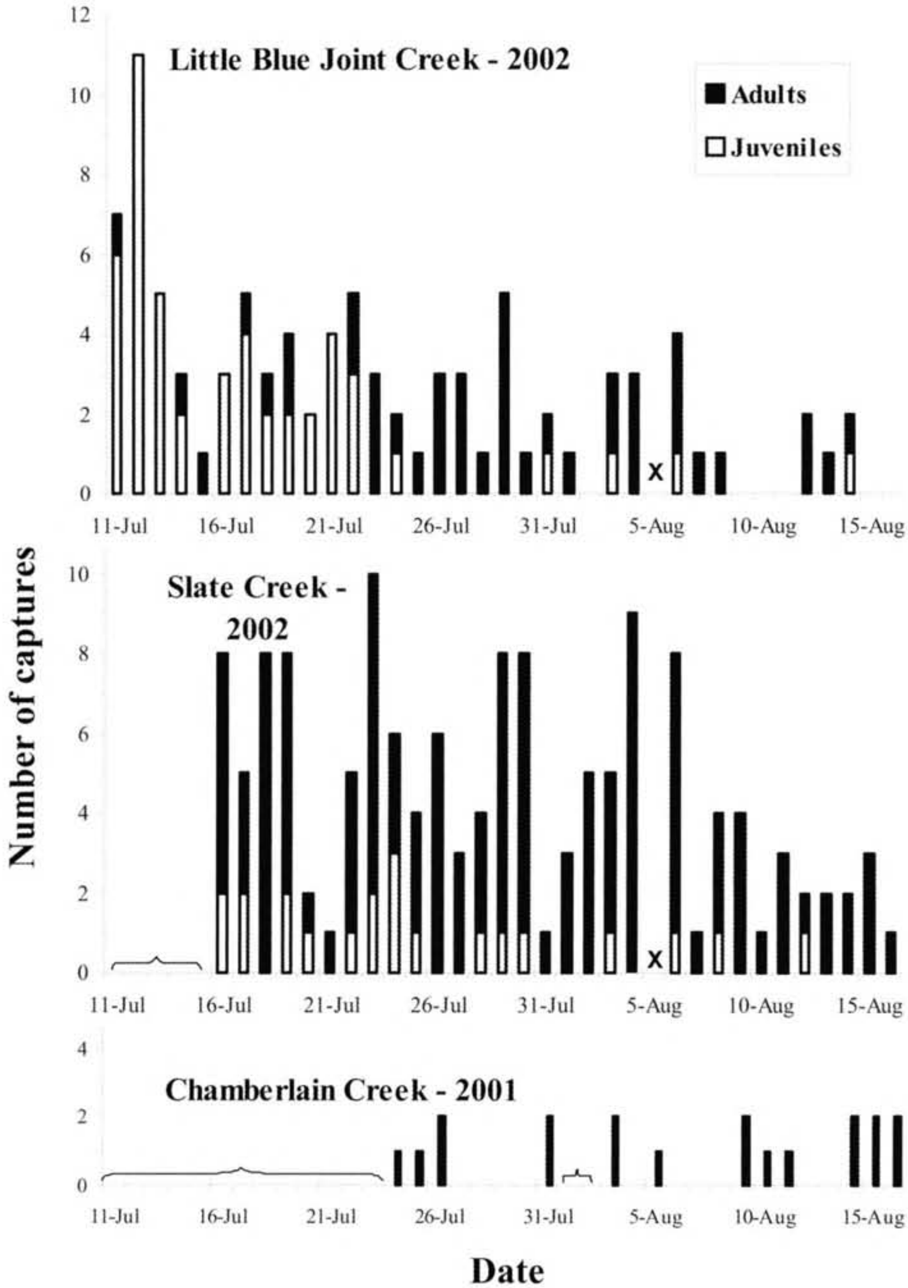

FIG. 2. Frequency of Boreal Toad captures in western Montana by stream, date, and life stage. Captures are from all traps in each stream. Brackets indicate dates when traps were not operated, and X's indicate when traps were operated but not checked. Although the Y-axis maximum varies among the graphs, the scales are identical.

Temporal trends in catch rates differed among streams. Captures of juvenile toads decreased significantly over the course of the study in Little Blue Joint ($N = 37$ days, $r = -0.65$, $P < 0.001$) and Slate creeks ($N = 32$ days, $r = -0.55$, $P = 0.001$). Captures of adult toads also decreased significantly as summer progressed in Slate Creek ($N = 32$ days, $r = -0.36$, $P = 0.04$), but not in Little Blue Joint Creek ($N = 37$ days, $r = -0.02$, $P = 0.89$). We made too few captures in Chamberlain Creek to test for trends.

Discussion.—Boreal Toads made extensive movements in streams. In three streams during two summers, we trapped numerous individuals that were moving downstream. During mid-summer, we detected movements as long as 1.5 km and maximum movement rates greater than 500 m/day. Moreover, the daily movement rates underestimated distances that toads would have traveled had our traps not interrupted their activity. No previous publications document Boreal Toads traveling long distances via water.

The observed movement patterns suggest that adult toads were using streams during their home range activities and that we were not documenting mass dispersal or migration behavior. Post-breeding migrations by toads are characterized by relatively rapid, straight, and directed movements, whereas summer home range

[b] Unsure which marked individual was recaptured.

movements are more haphazard (Kusano et al. 1995; Sinsch 1988, 1990). In our study, marked toads moved both up- and downstream, up to 21 days passed between captures of the same individual, and a fairly steady number of captures were made daily for more than a month.

Although the maximum detected movement distances we report are shorter than migratory or dispersal distances reported in other studies, these appear to be the longest home range movements yet observed. Female Boreal Toads in Idaho and Colorado made overland, post-breeding migrations of up to 2.3–2.4 km (Bartelt 2000; Muths 2003), but in Idaho, they subsequently established summer home ranges with a radius less than 100 m (P. Bartelt, pers. comm.). Likewise, in late summer, Campbell (1970a,b) observed movements of 900 m to overwintering sites, whereas summer home ranges averaged 317 m^2. In Wyoming, Carpenter (1954) documented total movements during July and August of up to 100 m and average daily movements of up to 13 m.

We might have observed longer summer home range movements for two reasons. First, toads inhabiting the moist riparian zone may tend to travel more extensively than those primarily using drier upland sites. Second, largely because of the confined, linear nature of streams, our methods might recapture toads moving long distances via streams more efficiently than traditional recapture methods on land (e.g., pitfall traps and drift fences).

Downstream movements via water might not be unusual, but merely overlooked, because nearly all bufonid movement studies have focused on terrestrial movements. Carpenter (1954) noted that some Boreal Toads in his study made "extended movements downstream." During the breeding season in Bulgaria, *Bufo bufo bufo* moved downstream at rates up to 568 m/day, similar to rates we observed, and traveled distances up to 2.5 km (Beshkov et al. 1986). During pre-breeding migrations, several *B. bufo* traveled downstream in a water-filled ditch to reach their breeding pond (Sinsch 1988 and pers. comm., February 2003).

All Boreal Toads were moving downstream when captured, which implies passive captures by downstream traps. *B. bufo bufo* also moved passively downstream, and males moving upstream in the water traveled short distances (up to 40 m, Beshkov et al. 1986). However, Boreal Toads occasionally bypassed downstream traps, indicating that they sometimes either traveled over land in a downstream direction or climbed over the nets while traveling downstream via water. Drifting downstream could provide several advantages to toads. Relatively passive downstream movements are energetically efficient. Also, during hot, dry weather (common during summers in the northern Rocky Mountains), the frequency and extent of anuran terrestrial activity is physiologically restricted by water balance and thermoregulation requirements (Sinsch 1990); traveling via water would allow for long-distance movements throughout summer, irrespective of weather or terrestrial conditions. Finally, aquatic movements may reduce exposure to terrestrial predators or provide an escape route.

We noted a weak decline in adult captures over time in Slate Creek but not in Little Blue Joint Creek, though sample size was

smaller in the latter. In a southern Utah population, terrestrial captures of adults near streams and on moist riparian slopes were higher in June and July than in August and September (Robinson et al. 1998). Such temporal declines in captures might result from a gradual shift toward more terrestrial habitats as summer progresses.

Our captures of juvenile toads are noteworthy because the behavior and habitat use of juveniles represents a large gap in our knowledge of Boreal Toads (McGee et al. 2002). We inferred from the SVLs that most juveniles captured were at least one year old. McGee et al. (2002) reported that juveniles migrate away from aquatic areas and use primarily terrestrial habitats after metamorphosis, but Carpenter (1954) observed juveniles occupying summer home ranges along small streams in Wyoming. We observed that at least some juveniles use aquatic habitats in early summer in western Montana. Captures of juvenile toads decreased by late July in Little Blue Joint and Slate creeks, and the temporal trends were highly significant. Based on the pattern, we infer that the lack of juvenile captures in Chamberlain Creek might be because of our later initiation of trapping there (23 July). The juvenile movements might represent dispersal, but further research is necessary to confirm this.

Although we show unequivocally that Boreal Toads travel in streams and sometimes move relatively long distances during midsummer in western Montana, our conclusions are limited by small numbers of marked toads, a relatively short study duration each summer, and lack of information about the more terrestrial components of the populations and of individual movements. Further study will be necessary to determine the proportion of each population that moves via streams as well as to ascertain terrestrial habitat use and total distances traveled by toads that use streams. Studies in other regions and of other species are needed to determine the prevalence of instream movements among bufonids. Research illuminating the benefits derived from aquatic movements will help to identify the conservation implications of the behavior.

Extensive travel via streams implies that any instream alteration that interferes with downstream passage might reduce juvenile and adult survival and be detrimental to Boreal Toad populations. Water diversions might influence the distribution of Boreal Toads, as Reese (1972) hypothesized for Tiger Salamanders (*Ambystoma tigrinum*), and screened diversions might completely obstruct downstream passage. For example, after an irrigation ditch on a Blackfoot River tributary, Montana, was screened to eliminate fish entrainment, more than 20 adult Boreal Toads were found dead in a concrete collection facility immediately upstream of the screen (R. Pierce, Montana Fish, Wildlife and Parks, Missoula, pers. comm.). Toads moving passively downstream were probably impinged on the screen by high water velocities and could not ascend the smooth, vertical, concrete walls to escape.

Ecological sensitivity analyses indicate that *B. boreas* population growth rates are highly vulnerable to decreases in postmetamorphic vital rates (e.g., juvenile and adult survival or the probability of laying eggs; Biek et al. 2002). Biek et al (2002) placed a high priority on research and management aimed at documenting and preventing alterations of natural, post-metamorphic vital rates. We recommend that managers consider the consequences of any habitat alterations that may increase mortality rates or disrupt movements of post-metamorphic Boreal Toads traveling in streams and riparian areas. In particular, we recommend designing and testing water diversion screens that allow anurans to escape.

If instream movements prove to be widespread, trapping in streams during early summer may be an effective tool for detecting Boreal Toads in drainages. Furthermore, juveniles have proven to be particularly elusive to researchers. Instream trapping potentially provides an easy means to obtain juveniles for marking, genetic analyses, or other research needs. In drainages where breeding areas are unknown, highly variable, dispersed, or difficult to reach, trapping of juveniles in streams may provide an alternative for confirming recent reproduction within a population.

In Situ Prevention of Anuran Fertilization: A Simple Method for the Detection of Sperm Competition with Potential for Other Applications

A. HETTYEY

e-mail (AH): hettyeya@freemail.hu

Sperm competition is recognized as an integral component of sexual selection, shaping life-history characteristics such as body size, morphology, physiology and behavior (Birkhead and Parker 1997). Sperm competition occurs when there is competition between the ejaculates of different males for the fertilization of a given set of ova (Parker 1970). Therefore sperm competition can be shown by detecting mixed paternity using molecular methods (Queller et al. 1993; Roberts et al. 1999), by direct observation of multiple male - single female copulations (Birkhead and Parker 1997; Jennions and Passmore 1993) and by comparing relative testis sizes and sperm traits among and within species based on sperm competition theory (Byrne et al. 2002; Harcourt et al. 1981). However, despite the relatively high number of proposed methods it remains difficult to assess sperm competition in external fertilizers, and our knowledge of the occurrence of sperm competition in externally fertilizing anuran taxa has remained scarce (Halliday 1998).

In the externally fertilizing anurans, the production of offspring often numbering in the hundreds or thousands may render molecular paternity analyses uneconomical. Similarly, comparative methods using testis sizes and sperm traits require large sample sizes (sometimes more than a hundred) of sacrificed animals (Jennions and Passmore 1993; Kusano et al. 1991). This method is also problematic because it does not provide direct evidence for sperm competition (Birkhead and Parker 1997). Behavioral observations (e.g., Fukuyama 1991; Kaminsky 1997; Kusano et al. 1991) also share the latter burden.

In order to demonstrate the occurrence of sperm competition in a rhacophorid frog, Jennions and Passmore (1993) proposed a simple method for the documentation of sperm release by peripheral males in multiple male amplexes. Before oviposition, they placed the amplexed male's lower body in a plastic bag (20 x 20 cm) and let the pair spawn in the presence of peripheral males. After embryonic development they counted hatching larvae and unfertilized eggs. In control treatments, where peripheral males were excluded, fertilization success was zero, whereas in the experimental trial, where peripheral males were present, hatching success was nearly 37%. They concluded that plastic bags act as effective condoms, and that peripheral males sired the tadpoles in experimental treatments. Their method, however, has some substantial weaknesses: Jennions and Passmore only performed

NATRIX NATRIX (European Grass Snake) **MALE COMBAT**. On 1 May 2001 during my field studies in the Stawy Milickie Nature Reserve (51°31'51"N, 17°20'12"E; Wroclaw, Poland) I observed two male (545 and 555 mm SVL) *Natrix natrix* engaged in combat in the presence of a female. Each male attempted to force his rival's anterior body to the ground. The snakes were often completely entwined. After three to five minutes the female moved into high grass, apparently in response to my presence, while the males continued to fight. After half a minute the males rapidly moved 60–70 cm forward, while still wrestling. This sequence was repeated several times before the two males suddenly ceased combat (ca. four minutes after the female left) and both began to follow the female's path while rapidly flicking their tongues. At this point I captured both males and measured and marked them for future identification.

Although *N. natrix* is common across most of Europe, this is the first report of combat in the species. The only previously reported form of male-male competition is tail wrestling (e.g., Madsen 1983. Oikos 40:77–82). Male combat can shape population structure and lead to the evolution of sexual size dimorphism (Shine 1993. *In* Seigel and Collins [eds.], Snakes: Ecology and Behavior, pp. 49–86. McGraw Hill, New York; Shine 1994. Copeia 1994:326–246) and is given much attention in snake studies. It is therefore difficult to conceive how such a conspicuous behavior has remained unreported in this common and widespread species. I believe that male combat is not ubiquitous in *N. natrix*, and expression of the behavior might vary geographically.

GEOGRAPHIC DISTRIBUTION

Instructions for contributors to Geographic Distribution appear in Volume 35, Number 1 (March 2004). Please note that the responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extension reports unless a thorough literature review has been completed.

CAUDATA

AMBYSTOMA MACULATUM (Spotted Salamander). USA: ILLINOIS: Hardin Co: Shawnee National Forest wildlife pond, 0.8 km N side FR 1726 and 0.3 km E Co. Rd. 700E (N37°33'38", W88°16'29"). 12 July 2004. Kurt J. Regester, Patrick T. McDonald, and Julius A. Frazier. Verified by Ronald A. Brandon. SIUC H-07765. Juvenile, metamorphosed in laboratory. New county record (Philips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, Champaign, Illinois. xii + 282 pp.).

Submitted by **KURT J. REGESTER, PATRICK T. MCDONALD**, and **JULIUS A. FRAZIER**, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA.

AMBYSTOMA TALPOIDEUM (Mole Salamander) USA: ARKANSAS: Clark Co: Populations of *Ambystoma talpoideum* in southwestern Arkansas appear to be isolated or disjunct from populations in northern Louisiana, northeastern Texas, and eastern Oklahoma (Trauth et al. 1993. Proc. Arkansas Acad. Sci. 47:154–156; Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. 3rd ed. Houghton Mifflin Co., Boston, Massachusetts, 509 pp; Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington, D.C., 587 pp; Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville, 421 pp.), and available information seldom defines whether populations are metamorphic or paedomorphic. Recent records (Caldwell and Tumlison 2003. Herpetol. Rev. 34:379; Tumlison and Campbell 2002. Herpetol. Rev. 33:143–144) prompted a survey for *A. talpoideum* in southwestern Arkansas, outside of its previously known range. Using dipnets and seines, we sampled aquatic habitats because aquatic *A. talpoideum* are more easily captured than the burrowing terrestrial adults (Bishop 1947. Handbook of Salamanders. Comstock Publishing Company, Inc, Ithaca, New York). All specimens are housed in the Henderson State University (HSU) Vertebrate Collections in Arkadelphia, Arkansas. Identifications were verified by Stan Trauth. Metamorphic salamanders were collected from temporary pools. Paedomorphic forms were collected in small, permanent, fishless ponds. Clark Co., 0.8 km NW Gurdon (S27 T9S R21W), 23 February 2002 and 15 March 2002, R. Tumlison, HSU 903–906 paedomorphic larvae, HSU1281 metamorphic form. Other paedomorphic and metamorphic specimens from Clark County locations are catalogued as HSU 1041, 1278, and 1299. Columbia Co., 3 km E McNeil (S16 T16S R20W), 25 April 1992, R. Tumlison, HSU1282, metamorphic larvae. Dallas Co., jct. County Roads 245 and 247 (S6 T9S R17W), 22 April 2003, B. Caldwell and T. Fulmer, HSU 1293, metamorphic larvae. An additional Dallas County specimen is catalogued as HSU 1294. Hempstead Co., County Rd. 32, 0.6 km from jct. with County Rd. 27 (S9 T9S R26W), 26 April 2003, B. Caldwell, HSU 1295, metamorphic larvae. Howard Co., 5 km W jct. Hwys 26 and 369, (S30 T8S R27W), 27 and 28 April 2003, B. Caldwell, HSU 1297, 1302, metamorphic larvae. Pike Co., 3 km SW of Murfreesboro, off Hwy 27 (S14 T8S R26W), 27 April 2002 and 26 April 2003, B. Caldwell and T. Fulmer, HSU 1274, 1300, metamorphic larvae. Additional Pike county vouchers are catalogued as HSU 1275–1277, 1279, 1296, and 1305.

We thank Stan Trauth for verifying identification of specimens, Fred Kizzia for permission to collect on his land, and Tobin Fulmer for field assistance.

Submitted by **BRIAN CALDWELL** and **RENN TUMLISON**, Department of Biological Sciences, Henderson State University, Arkadelphia, Arkansas 71999, USA; e-mail: tumlison@hsu.edu.

AMBYSTOMA TIGRINUM (Tiger Salamander). USA: FLORIDA: Calhoun Co: Florida Road 71, 10.1 km S of jct with Florida Road 20 at Blountstown (30°22.17'N, 85°5.75'W). 31 De-

cember 1969. D. Bruce Means and Clive J. Longden, spent female. Florida Museum of Natural History (UF 139288). TAYLOR Co: Florida Road S-14, 5.6 km S of bridge over Aucilla River (30°13.65'N, 83°52.27'W). 24 May 1970. D. Bruce Means. Large metamorph (UF 139289). Both specimens verified by Kenneth L. Krysko. First records for species in Calhoun and Taylor counties. The Taylor Co. record is the only known occurrence in the Coastal Lowlands physiographic province, about 13 km S of the Cody Scarp in the Florida panhandle. (Travis 1992, *In* Moler [ed.], Rare and Endangered Biota of Florida. Volume III. Amphibians and Reptiles, pp. 70–76. University Press of Florida, Gainesville).

Submitted by **D. BRUCE MEANS**, Coastal Plains Institute and Land Conservancy, 1313 Milton Street, Tallahassee, Florida 32303, USA.

NOTOPHTHALMUS PERSTRIATUS (Striped Newt). USA: GEORGIA: TAYLOR Co: Depressional wetland 1.3 km N of Georgia Highway 96, ca. 2.5 km W of Butler. 28 March 2004. John B. Jensen. GMNH 49903–04. Verified by Steve Johnson and Dirk Stevenson. First county record and first record within the Fall Line Sandhills physiographic region. Extends range ca. 130 km NW of nearest record (Wilcox Co., Georgia; Dodd and LaClaire 1995. Herpetol. Nat. Hist. 3:37–46). Many paedomorhpic adults captured by dip net. The shallow, open wetland is dominated by spikerush and rarely, if ever, dries completely. Off-site loblolly pine (*Pinus taeda*) plantations on deep, sandy soils surround the wetland.

Submitted by **JOHN B. JENSEN** and **NATHAN A. KLAUS**, Georgia Department of Natural Resources, Nongame-Endangered Wildlife Program, 116 Rum Creek Drive, Forsyth, Georgia 31029, USA (e-mail: john_jensen@dnr.state.ga.us).

NOTOPHTHALMUS VIRIDESCENS (Eastern Newt). USA: ILLINOIS: GALLATIN Co: Shawnee National Forest wildlife pond, SE side York Lane and 1.2 km E Pounds Hollow Road (37°36'14"N, 88°15'47"W). 21 March 2004. Patrick T. McDonald, Julius A. Frazier, and Kurt J. Regester. Verified by Ronald A. Brandon. SIUC H-07764. Adult male. New county record (Philips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, Champaign, Illinois. xii + 282 pp.).

Submitted by **PATRICK T. MCDONALD**, **JULIUS A. FRAZIER**, and **KURT J. REGESTER**, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA.

ANURA

ELEUTHERODACTYLUS PLANIROSTRIS (Greenhouse Frog). USA: MISSISSIPPI: HARRISON COUNTY: 1744 Magnolia St., Gulfport (30º24'12.3"N, 89º01'07.0"W) 5.42 km S of Interstate 10. 21 September, 24 September, and 4 October 2003. Abigail Dinsmore. Verified by Roy W. McDiarmid and Ronald I. Crombie. Mississippi Museum of Natural Science (MMNS 9274–76) and United States National Museum of Natural History (USNM 559976). Four adults of unknown gender were captured by hand under cover boards placed in a residential back yard. First record for the Mississippi Gulf Coast (Conant and Collins 1998. Reptiles and Amphibians: Eastern/Central North America, 3rd ed., expanded. Houghton Mifflin Co., Boston, Massachusetts, 509 pp.; R. L. Jones, pers. comm.); second specimen collected in Mississippi (first specimen collected by Ron Altig in Starkville, 421.79 km N (USNM 318495, collection date unknown). Appears established in Gulfport, as an individual overwintered under the cover board and 2–4 males have been heard calling every evening since 1 May 2004. About 20 adults have been observed since September 2003. Original introduction probably came from a nursery one block south that also contains the species and receives nursery plants from Florida and Louisiana.

Submitted by **ABIGAIL DINSMORE**, Department of Biological Sciences, Auburn University, Auburn, Alabama 36849, USA; e-mail: abidins@yahoo.com.

HYLA CINEREA (Green Treefrog). USA: TENNESSEE: MONTGOMERY Co: 1) Fort Campbell Military Reservation, N end of Los Banos Drop Zone (36°35'39"N,87°36'26"W). 14 May 2004. Scott Sutton and Tim Brown. Austin Peay State University Museum of Zoology (APSU 17544). Adult male on cattail (*Typha latifolia*) in open wetland. 2) Lylewood Road, 0.3 km E of Montgomery-Stewart county line (36°25'22"N,87°35'55"W). 19 July 2004. Josh Ennen and Josh Maloney. APSU 17652. Adult male on trunk of hardwood tree ca 0.5 m above water in floodplain swamp. 3) Lylewood Road, 4.0 road km S of Needmore in N floodplain of Cumberland River opposite river mile 109 (36°26'07"N,87°34'27"W). 19 July 2004. Josh Ennen and Josh Maloney. APSU 17653. Adult male on trunk of hardwood tree ca. 0.5 m above water in floodplain swamp. All specimens verified by A. Floyd Scott. These records represent the first verified reports of the species from Montgomery County and extend its range 27 km up the Cumberland River basin from the nearest reported site at Cross Creeks National Wildlife Refuge in Stewart County (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp.; [http://www.apsu.edu/amatlas/]; Therrell and Therrell 1999. Herpetol. Rev. 30:172). Collections were made under authority of Tennessee Wildlife Resources Agency Permit 1662; field work was supported in part by Austin Peay State University's Center for Field Biology.

HYLA PHYLLOGNATHA (NCN). ECUADOR: PROVINCIA DE ZAMORA-CHINCHIPE: Numbami and Romerillos Bajo, Jamboe River basin, Podocarpus National Park (ca. 04°14'S, 78°56'W, 1500–1700 m). 28–30 April 1999. F. Nogales and D. Almeida. Universidad San Francisco de Quito/Fund. Herpetológica Orcés, Quito (FHGO-USFQ 2346, 2434). Verified by Jean-Marc Touzet. Previously known along the Amazonian slopes of the Andes and associated ranges in Colombia, Ecuador, and Peru (Duellman 1972. Occ. Pap. Mus. Nat. Hist. Univ. Kansas 11:1–31; Ruiz-Carranza and Lynch 1982. Caldasia XIII [64]: 647–671; Frost 2002 Amphibian Species of the World. V2.21 [15 July 2002]. <http://research.amnh.org/herpetology/amphibia/index.html> [Accessed: 19 July 2004]). There is a gap of ca. 500 km between the Ecuadorian records in the provinces of Sucumbíos, Napo, Pastaza, Tungurahua, and Morona-Santiago, and the Peruvian records in the departments of San Martín, Ucayali, Cusco, Pasco, and Junín (Duellman, *op. cit.*; Lehr 2001. Herpetol. Rev. 32:130–132). Specimens reported herein constitute the first locality within the province of Zamora-Chinchipe, partially filling the gap between Ecuadorian and Peruvian records. This locality is the westernmost record for the species, extending its range ca. 230 km SSW from the nearest locality in the province of Morona-Santiago (Macas; Duellman, *op. cit.*).

Submitted by **DIEGO F. CISNEROS-HEREDIA**, College of Biological and Environmental Sciences, Universidad San Francisco de Quito, Ave. Interoceánica y calle Diego de Robles, Campus Cumbayá, Edif. Maxwell, Casilla Postal 17-12-841, Quito, Ecuador; e-mail: diegofrancisco_cisneros@yahoo.com.

HYLA VERSICOLOR (Gray Treefrog). CANADA: ONTARIO: THUNDER BAY DISTRICT. Ware Twp., 8.5 km NE of Hwys 11/17 and 102 intersection (NAD 27: UTM Zone 16: N5386700m, E308100m). 8 June 2002. Wayne F. Weller and Alessandra Weller. Royal Ontario Museum (ROM 39374 [segment 26], audio cassette tape). All tape recordings verified by Ross D. MacCulloch. Six individuals calling from marsh and pond near mixed woods at 2235 h. THUNDER BAY DISTRICT. Oliver Twp., 11.0 km SW of Hwys 591 and 589 intersection (NAD 27: UTM Zone 16: N5374600m, E319000m). 6 June 1999. Wayne F. Weller and Alessandra Weller. ROM 38443 [segment 5], audio cassette tape. Two individuals calling from cattail pond near mixed woods at 2250 h. THUNDER BAY DISTRICT. McIntyre Twp., 6.7 km NW of Hwy 11/17 and 130 intersection (NAD 27: UTM Zone 16: N5367800m, E324700m). 28 May 1999. Wayne F. Weller and Alessandra Weller. ROM 38443 [segment 2], audio cassette tape. Three individuals calling from flooded roadside ditch at 2215 h. THUNDER BAY DISTRICT. Paipoonge Twp., Mt McKay, Thunder Bay (NAD 27: UTM Zone 16: N5357800m, E330900m). 27 May 1999. Wayne F. Weller and Alessandra Weller. ROM 38443 [segment 1], audio cassette tape. Four or five individuals calling from marsh at 2230 h. THUNDER BAY DISTRICT. Devon Twp., 4.3 km SE of Hwy 593 and Arrow River intersection (NAD 27: UTM Zone 16: N5331200m, E289400m). 18 June 1997. Wayne F. Weller. ROM 32576, audio cassette tape. Calling from spruce swamp at 2330 h. THUNDER BAY DISTRICT. Lismore Twp., Hwy 593, 1.6 km SW of Strange/Lismore Twp boundary (NAD 27: UTM Zone 16: N5343700m, E284800m). 18 June 1997. Wayne F. Weller. ROM 32576, audio cassette tape. Five to ten individuals calling from marsh at 2240 h. The documented eastern range limit in northwestern Ontario is represented by a specimen from the Shebandowan Lakes region (ROM 9911 – June 1964). The 6 records noted represent an extension of the documented range 35 km E, 70 km ESE, and 60 km SSE of the Shebandowan Lakes locality. Within an approximate 3500 km^2 area (enveloped by these 6 records) extending to the Lake Superior coastline and southward to the Minnesota/Ontario border, 8 additional localities have been documented with taped calls (June 1997, June 1999, May and June 2002. Wayne F. Weller and Alessandra Weller. ROM 39374 [segments 22, 23, 25, 27]; ROM 38443 [segment 4]; ROM 32576 [3 tape segments]). Collectively, these 14 documented localities substantiate observations made since 1997 at 201 localities within the 3500 km^2 area during field investigations for "atlasing" (Oldham and Weller 2000. Ontario Herpetofaunal Atlas. Natural Heritage Information Centre, Ontario Ministry of Natural Resources, Peterborough, Ontario, Canada. Website mnr.gov.on.ca/MNR/nhic/herps/ohs.html) conducted by WFW and others, and for population and environmental studies conducted by SJH. THUNDER BAY DISTRICT. Unnamed Twp., Swede Island, S of Black Bay Peninsula, Lake Superior (NAD 27: UTM Zone 16: N5371600m, E397500m). 19 July 2000. Brian Ratcliff and others. ROM 39423, photograph. Verified by Ross D. MacCulloch. This represents the first documentation on islands along the northern coastline of Lake Superior, and extends the range 125 km E of the Shebandowan Lakes locality.

Submitted by **WAYNE F. WELLER**, 250 Chercover Drive, Thunder Bay, Ontario P7G 1A2, Canada, and **STEPHEN J. HECNAR**, Department of Biology, Lakehead University, 955 Oliver Road, Thunder Bay, Ontario P7B 5E1, Canada.

HYPEROLIUS ACUTIROSTRIS (NCN). EQUATORIAL GUINEA: PROVINCE WELE-NZAS: Parque Nacional Los Altos de Nsork: 01°13'52.4"N, 11°00'53.4"E, 550 m asl. 30 March 2003. Jorge de Leon. Yale Peabody Museum of Natural History (YPM 8000). Verified by Robert Drewes. New country record. This species was previously only known from Cameroon (Schiøtz 1999. Treefrogs of Africa. Edition Chimaira, Frankfurt, Germany). This specimen extends the known range of this species by ca. 300 km S. The Guinea collecting site is proximal to the Gabon border and the prevailing rainforest habitat extends uninterrupted across the border. Therefore, it likely that this species will be found in

Gabon as well.

KASSINA SENEGALENSIS. MAURITANIA: WILAYA ASSABA: Bou Bleï'Îne (17°0'34"N, 10°59'24"W). J. M. Padial. 26 May 2002. Juvenile. Museo Nacional de Ciencias Naturales (MNCN 41782). Verified by Ignacio de la Riva. First country record of the family (Hyperoliidae). The specimen was found under a trunk on the shore of an isolated wetland in the Saharan border, surrounded by the Sahel Savannah. The area was largely xeric under the strong influence of extremely dry condition of Sahara but with a seasonal rainfall. Other amphibian species found there include *Bufo xeros*, *Hoplobatrachus occipitalis*, and *Tomoptera cryptotis*.

MYERSIELLA MICROPS. BRAZIL: MINAS GERAIS. Municipality of Cristina (22°13'05"S, 45°15'25"W), 1150 m. 27 March 2004. A. F. B. Junqueira. Coleção Científica de Vertebrados do Laboratório de Zoologia da Universidade de Taubaté, UNITAU, Taubaté, São Paulo, Brazil (IAM/CCLZU 1429, male SVL: 22.2 mm). 1 April 2004. A. F. B. Junqueira (IAM/CCLZU 1430–1431, 2 subadult males SVL: 19.3 and 19.6 mm). 14 May 2004. A. F. B. Junqueira and F. B. R. Gomes, (IAM/CCLZU 1432, female SVL: 37.8 mm; 1433, subadult male SVL: 18.6 mm) and Célio F. B. Haddad collection, deposited in Departamento de Zoologia, Universidade Estadual Paulista, Rio Claro, SP, Brazil (CFBH 7308, female SVL: 33.2 mm). Verified by C. F. B. Haddad. Previously known from coastal Atlantic forest of southeastern Brazil, at low and moderate elevations in Espírito Santo, Rio de Janeiro, Serra do Mar in São Paulo and north of Minas Gerais, (Heyer et al. 1990, Arq. Zool. Univ. São Paulo 31[4]:231–410; Izecksohn and Potsch de Carvalho-e-Silva. 2001, Anfíbios do Município do Rio de Janeiro, Editora UFRJ. 148 pp; Hartmann et al. 2002, J. Herpetol 36:509–511; Frost 2002, Amphibian Species of the World: An online reference V2.21, http://research.amnh.org/herpetology/amphibia/index.html; Feio et al. 2003, Herpetol. Rev. 34:259). This record for southern Minas Gerais, in southeastern Brazil, extends known distribution ca. 480 km SW from Caratinga, MG (Feio et al., *op. cit.*); ca. 300 km NNW from the Serra do Mar (Izecksohn and Potsch de Carvalho-e-Silva, *op. cit.*; Hartmann et al., *op. cit.*) and ca. 450 km NE of Boracéia (Heyer et al. 1990, *op. cit.*). This is also the first record for the Serra of Mantiqueira.

OSTEOPILUS SEPTENTRIONALIS (Cuban Treefrog). USA: FLORIDA: GADSDEN CO: Havana, house at 1241 Tallavana Trail (30.593°N, 84.460°W). 17 July 2004. Beth Bloomquist. Verified by Kenneth L. Krysko. Florida Museum of Natural History, University of Florida (UF 141849). One adult female (76 mm SVL) was collected from inside a plastic container on the back deck of the house. The two most likely scenarios for the frog's arrival at this isolated site are that it was transported in: 1) one of several potted orchids purchased in Sarasota, Florida in September 2003, or 2) a vehicle from Sarasota in April 2004. *Osteopilus septentrionalis* is extremely common in Sarasota in the southwestern Florida peninsula. This specimen appears to be the first of the species confirmed from the Florida panhandle.

Although there are records of Cuban Treefrogs in the literature for three counties in the Florida panhandle, for reasons outlined below these previous records should be disregarded. Ashton (1976. Florida State Mus. Herpetol. Newsletter 1:1–16) reported Cuban Treefrogs from Leon and Washington counties and indicated that voucher specimens were deposited in the Florida State Museum (now known as the Florida Museum of Natural History [FLMNH]). However, no specimens from these counties exist in the FLMNH (K. Krysko, pers. comm.). It is most probable that Ashton (1976, *op. cit.*) made a mistake when compiling the species list of county records that comprises 11 pages of the newsletter. In their map of Cuban Treefrog distribution in Florida, Meshaka et al. (2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publ. Co., Malabar, Florida, 155 pp.) include Ashton's unsubstantiated records and an additional record for Holmes Co. in the western panhandle. The source of the Holmes Co. location is given as Meshaka (1996. Herpetol. Rev. 27:37–40). However, Meshaka (1996, *op. cit.*) does not mention any Cuban Treefrogs from Holmes County. Therefore, the Meshaka et al. (2004, *op. cit.*) record is also questionable. A search for *O. septentrionalis* vouchers in national and southeastern U.S. regional collections failed to locate a record of this species from any county in the panhandle. Thus, the Gadsden Co. specimen reported here is the first vouchered specimen of *O. septentrionalis* from the Florida panhandle.

PLEURODEMA NEBULOSUM (Mendoza Four-eyed Frog). ARGENTINA: NEUQUÉN: DEPARTAMENTO AÑELO (38°21'S, 68°47'W): Arroyo Ojos de Agua. 14 November 1976. O. de Ferrariis. Museo Argentino de Ciencias Naturales "Bernardino Rivadavia," Buenos Aires, Argentina (MACN 36078); Auca Mahuida (37°53'S, 68°31'W). April 1945. O. Adams (MACN 7980). DEPARTAMENTO CATAN-LIL (39°33'S, 70°35'W): Charahuilla. 4 February 1973. O. de Ferrariis. Colección del Centro Nacional de Investigaciones Iológicas, housed at MACN (CENAI 7081). First province records, extend the known distribution 275 km W from closest record (General Roca, La Pampa province; Gallardo 1965. Rev. Mus. Arg. Cs. Nat. B. Rivadavia [Zool.] 1[2]:57–77). SALTA: DEPARTAMENTO CAFAYATE (26°06'S, 65°57'W): Cafayate. 11 January 1991. J. McGuire. Fundación Miguel Lillo, Tucumán, Argentina (FML 5245); Cafayate, on Ruta Nacional Nº 68, between 8 and 12 km N of its intersection with Ruta Provincial Nº 40. 11 January 1991. R. Etheridge (FML 5246, three specimens); Cayafate, los Médanos. 2 January 1993. N. Abdala (FML 5232, three specimens). DEPARTAMENTO SAN CARLOS (25°53'S, 65°56'W):

San Carlos, ca. 10 km E from Animaná. 4 January 1993. E. O. Lavilla (FML 5234, two specimens). First vouchered specimens, previously mentioned from Salta Province by Lavilla (1999. Anfibios. *In* Lavilla and González [eds.], Biodiversity of Agua Rica, Catamarca, Argentina. Fund. M. Lillo - BHP Copper). DEPARTAMENTO ANTA (24°55'S, 64°28'W): Finca Los Colorados. 13 January 2000. E. O. Lavilla and R. Heyer (FML 9094–96). First Department record. Salta Province reports extend the known distribution 350 km NE from previous closest record (Andalgalá, Catamarca province; Lavilla 1999, *op. cit.*). TUCUMÁN: DEPARTAMENTO TAFÍ DEL VALLE: Quilmes (26°30'S, 66°00'W). 18 January 1975. R. Laurent and C. Halloy (FML 2427, 43 specimens). New province record, cited by Laurent to Tucumán Province (1969. Acta zool. lilloana 25[7]:81–96). This report extends known distribution 102 km NE from closest record (Andalgalá, Catamarca Province; Lavilla 1999, *op. cit.*). Boundary between CATAMARCA and TUCUMÁN provinces: Arroyo los Médanos, between Santa María and Amaicha del Valle. 20 January 1975. R. Laurent and C. Halloy (FML 2425, three specimens); ca. 10 km from bridge of Santa María River. 25 January 1975. R. Laurent and C. Halloy (FML 2429, two specimens). New record for this area, extends known distribution ca. 111 km N from closest record (Andalgalá, Catamarca Province; Lavilla 1999, *op. cit.*). All specimens verified by Esteban O. Lavilla. The previously known range of this species includes the western Argentinian provinces from Catamarca to Río Negro (Cei 1980. Amphibians of Argentina. Monit. Zool. Ital. [N.S.] Monogr. 2: [i-xii] + 1–609; Aun and Martori 1999. Herpetol. Rev. 30:231) and Tucumán Province (Laurent 1969, *op. cit.*).

PSEUDACRIS CRUCIFER (Spring Peeper). USA: TEXAS: GREGG CO.: Three specimens were collected from a small pond on private land, ca. 9 km E of Kilgore. (32°22'23"N, 94°47'35"W). 28 February 2004. Collected by Shelby C. Braman. Specimens deposited with the Texas Cooperative Wildlife Collection (TCWC 88174–88176). Verified by Ronald L. Gutberlet, Jr. Upland Chorus Frogs (*P. triseriata*) in amplexus and Bullfrogs (*Rana catesbiana*) were also collected in this particular pond. All three species were abundant and chorusing. These specimens represent the first Gregg County records for *P. crucifer* and partially fill the distribution gap of Gregg, Rusk, and Panola Counties of east Texas (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station, Texas. 421 pp.).
